Thyroglossal cyst is essentially a mid line structure developing from remnants of the thyroglossal duct, and moves upwards when the tongue is protruded It is of cosmetic rather than medical significance

4 *Cardiovascular signs* Vasodilatation in the skin and muscle is nearly always present and may be recognised by hot extremities distended fore arm veins throbbing digital vessels capillary pulsation modified water hammer pulse and raised pulse pressure Tachycardia is the rule and persists during sleep (Boas, 1932) The action of the heart is vigorous the cardiac impulse being forceful and displaced a little to the left, and the heart sounds slapping A systolic murmur may be heard at apex or base and a thrill may be felt on compressing the carotid or subclavian artery Rarely a functional mitral diastolic murmur may be heard

Auricular fibrillation may be initiated by overdosage of thyroxine in patients with normal hearts It occurs in 10 per cent of all cases of thyrotoxicosis and in 84 to 96 per cent of those with cardiac failure and may be paroxysmal or persistent It is rare in young subjects but becomes progressively frequent with advancing years During attacks the ventricular rate is apt to be very fast and the patient may complain of violent palpitations

Fig 20 05—Skiagram showing slight prominence of the aortic knuckle and of the left pulmonary arc in a case of thyrotoxicosis

Cardiac enlargement and failure are also relatively late developments and are unusual with normal rhythm but often follow the onset of auricular fibrillation An appreciable proportion of such cases (over 50 per cent according to Magee and Smith 1935) are complicated by hypertension or other forms of heart disease

X rays may show slight prominence of both the aortic knuckle and left pulmonary arc (Parkinson and Cookson 1931) and general fullness of all chambers probably due to the high cardiac output (fig 20 05) The electrocardiogram may be within normal limits unless it shows auricular fibrillation or the voltage of *P* and *QRS* may be augmented (fig 20 06)

5 *Other and less constant features* Neurological signs are rare they include exophthalmic ophthalmoplegia and myasthenia—sometimes resembling myasthenia gravis but not responding to prostigmine Curious-

patches of local myxœdema occasionally occur on the legs koilonychia has been described and the skin may be unduly pigmented

Decalcification of bone is not uncommon a negative calcium and nitrogen balance may be demonstrated the blood cholesterol may be rather low sugar tolerance may be reduced and impairment of hepatic function has been reported

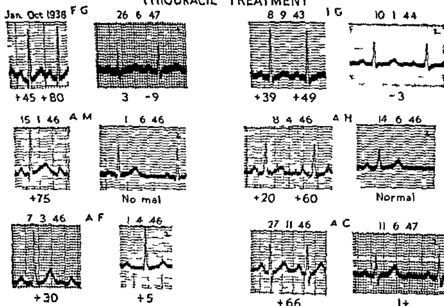

Fig 20 06—Ele trocardiog ams (all lead 2) showing relatively high voltage P and QRS waves in 6 ases of thyrotoxico is After treatment with thiouracil the voltage falls considerably The B M R is recorded und r each record

SPECIAL INVESTIGATIONS

1 *The basal metabolic rate* (B M R) introduced by Magnus Levy in 1895 has proved a useful guide to the degree of hyperthyroidism and is a measurement of the amount of oxygen consumed by the patient per minute when at complete rest i e fourteen hours after the last meal and after lying down undisturbed for at lea t half an hour The patient breathes in and out of a closed system containing equal proportions of air and oxygen for ten minutes carbon dioxide being removed by means of soda lime the amount of gas disappearing from the system represents the total amount of oxygen consumed This is then recorded in terms of oxygen consumption per square metre of body surface per minute and expressed as a percentage of what a normal person of the same age and sex would require In thyrotoxicosis the B M R commonly ranges between plus 10 and plus 80 per cent Read s formula for estimating the B M R by the pulse rate and pulse pressure is unreliable and worth no more than the knowledge that the com

bination of tachycardia and a bounding pulse suggests a raised cardiac output (Read s formula is B M R equals ¾ [pulse rate plus ¾ pulse pressure] minus 72)

It should be understood that a single B M R of plus 20 per cent does not necessarily mean that the disease is milder than one with a B M R of plus 40 per cent for the course of thyrotoxicosis is variable Serial readings may give a truer picture of the degree of activity Another important point is that auricular fibrillation and heart failure are more often associated with low grade activity acting over a long period of time, than with acute thyrotoxicosis so that the level of the B M R is no guide to the degree of cardiac disability

The B M R is more difficult to interpret when measured for diagnostic purposes but if it is below plus 10 per cent thyrotoxicosis is improbable High readings however may be due to faulty basal conditions o to other causes such as leukæmia and relatively high readings may be obtained in congestive heart failure of any etiology According to Foote *et al* (195) 23 per cent of thyrotoxic patients have basal metabolic rates within the normal range

2 *The administration of* 10 *minims* (0 6 *ml*) *of Lugol s iodine* three times daily for a week or ten days may be used as a test for hyperthyroidism in two ways (1) to see whether it unmasks a goitre, for a hyperplastic gland enlarges and hardens under its influence (2) to determine its effect on the sleeping pulse body weight and B M R for these are beneficially influenced in thyrotoxic cases but not when the B M R is raised from other causes

3 *Measurements of the cardiac output peripheral blood flow and circulation time* provide valuable data Outputs of 8 to 12 litres per minute are usual and are correlated more with the heart rate than with the venous filling pressure When the heart fails the output drops usually to subnormal levels The fore arm blood flow is invariably increased and usually remains so when the cardiac output falls as a result of failure moreover the augmented flow does not subside for several weeks after the B M R has been restored to normal by means of thyroidectomy or thiouracil therapy (Howarth 1948) Circulation times under 10 seconds are characteristic (Goldberg 1938) and may remain well within normal limits when there is systemic congestion

The demonstration of a high cardiac output at rest places a case in the hyperkinetic group the differential diagnosis then includes severe anæmia anoxic cor pulmonale arterio venous aneurysm Paget s disease of bone secondary carcinoma involving the liver or other serious hepatic disorders and beri beri The majority of these can be recognised or excluded at once on clinical grounds

4 *Urinary creatine test* Up to 200 mg of creatine may be excreted daily in the urine by normal women and children in an irregular manner but very little if any by normal men Excessive creatinuria occurs during

pregnancy and increased amounts may appear in the urine of either sex in fevers wasting diseases and certain muscular dystrophies

Most thyrotoxic subjects excrete an excess of creatine (Sohval King and Reiner 1938) and its detection may be used as a diagnostic test if the above considerations are borne in mind Thyroid responsibility may be proved by the disappearance of creatinuria within ten days of first giving iodine or thiouracil treatment (fig 20 07) (Schrire 1938) On the other

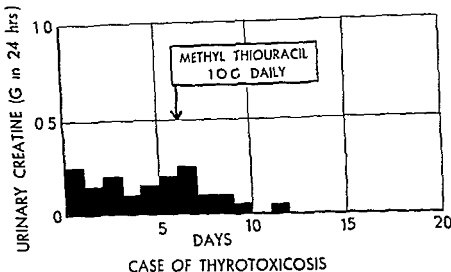

Fig 20 07—Effect of thiouracil on the excretion of creatine in the urine

hand, absence of creatinuria does not exclude thyrotoxic heart disease, for such cases are apt to be associated with low grade toxicity acting over a long period of time rather than with a high degree of hyperthyroidism and creatine excretion may be well within normal limits

5 *Electrocardiography* may reveal abnormally high voltage of P and QRS (fig 20 06) as previously stated It may also be of value in proving the nature of an irregularity of rhythm or in excluding certain other causes of a hyperkinetic circulation (e g pulmonary heart disease and anæmia)

6 *Radioactive iodine* (I^{131}) which has a half life of eight days may be given orally or intravenously in single test doses of 10 to 30 microcuries to see how the thyroid gland deals with it (Keating *et al* 1945) The body does not distinguish between radio iodine and ordinary iodine The concentration of I^{131} in liquids such as the plasma and urine can be estimated by means of liquid counters that detect the beta ray emanation the concentration of I^{131} in any tissue zone can be estimated by means of surface Geiger Muller counters that detect gamma rays which unlike the soft beta rays penetrate the skin Normally the concentration of I^{131} in the thyroid gland reaches a maximum of about 33 per cent of the test dose in two or three days and then slowly declines (Myant and Pochin 19

Simultaneously about 60 per cent of the test dose is excreted in the urine within two days, the actual quantities extracted by the thyroid or excreted in the urine depending on the concentration of I^{131} in the plasma The plasma concentration necessarily falls to a very low level by the end of the second day for 93 per cent of the test dose is by then in the thyroid gland or excreted in the urine Subsequently however I^{131} again appears in the plasma as protein bound radiothyroxine The more active the thyroid gland the greater the quantities of iodine extracted and radiothyroxine manufactured the quicker the turn over and the less iodine excreted in the urine (Myant and Pochin 1949) the more inactive the gland the more does the reverse hold true

All radioactive iodine tests of thyroid function are based on these four fundamental principles

(i) *The concentration of I^{131} in the thyroid gland* at the end of four hours in normal subjects averages 20 to 25 per cent of a 10 microcurie *test* dose (range 10 to 40 per cent) in thyrotoxicosis it is usually 40 to 90 per cent (Wayne 1954) This type of test is sometimes expressed as a neck/thigh ratio the concentration of I^{131} in the thigh serving as a control so that the amount of iodine in the thyroid gland can be distinguished from the amount in the soft tissues of the neck (Pochin 1950)

(ii) Thyroxine as manufactured and released by the thyroid gland is closely bound to protein and when circulating in the plasma may therefore be precipitated with the plasma proteins Radiothyroxine of course is similarly protein bound As stated above the amount of protein bound radiothyroxine circulating in the plasma 24 to 48 hours after a 25 micro curie test dose of I^{131} is negligible in normal subjects being less than 0 4 per cent of the test dose per litre of plasma at the end of 48 hours and usually less than 0 1 per cent (Goodwin *et al* 1951) in thyrotoxicosis however it ranges between 0 04 and 3 5 per cent per litre (Wayne 1954)

(iii) The *thyroid clearance* test is the best measure of the speed at which the thyroid gland extracts iodine from the plasma After an intravenous test dose of 30 microcuries of I^{131} the thyroid gland normally extracts about 6 per cent of the test dose per hour when the plasma concentration is around 4 per cent of the test dose per litre this means that 1 5 litres of plasma are cleared of radio iodine per hour or that the thyroid clearance is 25 ml per minute *In* normal subjects the thyroid clearance ranges between 7 and 42 ml per minute *In* thyrotoxicosis however iodine extraction is speeded up and the thyroid clearance averages 240 ml per minute ranging between 80 and 500 (Pochin 1950)

(iv) *The quantity of I^{131} excreted in the urine* is proportional to its con centration in the plasma provided renal function is unimpaired Normally over 40 per cent of a 10 microcurie test dose is excreted in 24 hours whereas in cases of thyrotoxicosis less than 25 per cent is usually excreted in this time (Pochin 1950) This test is an indirect measure of the amount of I^{131} extracted by the thyroid gland during the 24 hours for the more

extracted the lower the plasma concentration and therefore the less excreted in the urine Mason (1949) and Fraser *et al* (1953) have shown that the urinary excretion test is more helpful if the amount of I[131] excreted during the first six or eight hours is considered separately for excretion is only diminished when the plasma concentration has fallen owing to increased thyroid extraction In practice the amount of I[131] excreted from the sixth or eighth to the twenty fourth hour after the test dose seems to be the most sensitive index of thyroid activity In normal subjects Mason (1949) found that 10 to 25 per cent of the test dose was excreted during the critical 6 to 24 hour period whereas in cases of thyrotoxicosis less than 4 5 per cent was excreted during this time

According to Wayne (1954) the most reliable of these tests is the estimation of protein bound radiothyroxine in the plasma at 48 hours thyroid clearance coming second and the amount of I[131] taken up by the thyroid gland in four hours third

TREATMENT

The most satisfactory method of treating thyrotoxic heart disease is subtotal thyroidectomy as developed by Dunhill (1908 1929 1937) The best results are obtained when physician and surgeon work in the closest harmony success depending as much upon the skill and judgment of the physician as upon the experience and dexterity of the surgeon (Fraser and Dunhill 1934) adequate premedication being all important

The patient should be put to bed and fed on a liberal and nourishing diet The addition of 5 to 10 mg of aneurin daily may be helpful on the grounds that an abundant supply of this vitamin is needed for the increased carbohydrate metabolism Fatigue and weakness may respond to 50 mg of pyridoxine daily (So kin and Levine 1944) Phenobarbitone ½ a grain (32 mg) t d s or potassium bromide 10 grains (0 64 G) t d s may also be prescribed with benefit and a nocturnal sedative is usually necessary

During this preliminary stage of treatment which usually induces some remission of symptoms the degree of thyrotoxicosis may be assessed clinically and by means of the special tests detailed above Prior to the introduction of thiouracil and the newer antithyroid drugs iodine was then given by mouth in doses of 10 minims (0 06 ml) of Lugol s solution three times daily preferably in milk Within ten days there was usually marked improvement the pulse rate fell the B M R was lowered and the patient felt better (Waller 1914 Plummer 1923) The moment for operation was usually ten to fourteen days after beginning iodine Nowadays however preliminary treatment with antithyroid drugs is preferred (*vide infra*)

The introduction of thiouracil by Astwood (1943) following the discovery by the Mackenzies (1941) that the administration of sulphaguanidine to rats caused thyroid hyperplasia and reduction of colloid has proved an important therapeutic advance Thyroid hyperplasia was attributed to increased production of thyrotropic hormone by the anterior pituitary

endeavour to compensate for deficiency of thyroid hormone brought about by sulphaguanidine Astwood found that many substances had a similar effect including all the sulphonamides, *p* aminobenzoic acid thiourea and its compounds and that of these thiouracil offered the best prospects being potent and relatively non toxic It is held that thiouracil and the other substances mentioned act by interfering with the union of iodine and tyrosine and so prevent the formation of di iodotyrosine a known precursor of thyroxine (Riker and Wescoe 1945) The histological appearance of the thyroid gland under their influence resembles the hyperplastic gland of iodine deficiency

Since then several other more potent and less toxic antithyroid drugs have been developed and several of them have superseded thiouracil These include methylthiouracil propylthiouracil and neomercazole The initial dose of thiouracil and its derivatives is 50 to 100 mg three times daily for two weeks followed by 25 to 50 mg two or three times daily thereafter (Astwood 1949) Neomercazole (Lawson *et al* 1951) is in a different category the equivalent dose being only 10 mg two or three times daily initially and 5 mg once or twice daily for maintenance

Extensive trials have established what may be expected from treatment with antithyroid drugs (Astwood 1944 Williams 1944 1946 Himsworth 1948 Goodwin *et al* 1954) Amelioration of all symptoms except exophthalmos and those due to the size of the goitre and objective evidence of reduced thyroxine output can be demonstrated in 90 per cent of cases but when the drug is withheld after a year or so there is a 2 1 chance in favour of relapse within forty eight months (Goodwin *et al* 1954) Moreover toxic symptoms such as fever, dermatitis purpura, adenopathy and agranulocytosis which develop in 13 per cent of cases having thiouracil (Van Winkle 1946) prevent long term treatment even with the less toxic propylthiouracil or neomercazole in about 5 per cent of cases The mortality from agranulocytosis due to thiouracil is 0 5 per cent (Moore 1946) Increasing exophthalmos and the development of a highly vascular expanding goitre are attributed to over activity of the pituitary thyrotropic hormone in response to subnormal thyroxine output and may be prevented by the simultaneous administration of a maintenance dose of *thyroid (Williams and Bissell 1943) or thyroxine (Fraser and Wilkinson* 1953)

Despite the high relapse rate antithyroid drugs may be the treatment of choice in acute cases of primary Grave s disease in young people *It is* usually unsatisfactory in the long run in well established cases of toxic nodular goitre relapse in this group being more or less inevitable when the drug is withheld

The antithyroid drugs however have proved invaluable for preparing patients for partial thyroidectomy and if l thyroxine sodium 0 1 to 0 3 mg daily or thyroid gr 1 to 3 daily is given in addition increased vascularity of the gland can be avoided Lugol s iodine may be used

instead of thyroid for the same purpose (Means 1946) but is probably less efficient The great advantage of the antithyroid drugs over Lugol s iodine in preparing patients for operation is the abolition of the sense of urgency, for patients do not relapse while taking antithyroid drugs

Cardiac complications do not contraindicate partial thyroidectomy (Dunhill 1937) More careful preparation however is needed auricular fibrillation must be controlled and heart failure relieved before it is safe to operate but normal rhythm should not be deliberately restored at this stage

The commonest post operative complication used to be paroxysmal auricular fibrillation with rapid ventricular rate but this is less frequent if the patient is prepared with an antithyroid substance It should not occasion undue alarm for the rhythm usually reverts to normal spontaneously within 48 hours If auricular fibrillation persists however whether previously well established or of recent onset every effort should be made to restore normal rhythm by means of quinidine before the patient leaves hospital The risk of embolism is slight perhaps because the hyperkinetic circulation lessens the chance of venous thrombosis

Treatment with radioactive iodine

Deep X ray therapy was curative in about a third of cases resulted in some improvement in a third and was without benefit in the remainder (Means and Holmes 1923) In the treatment of thyrotoxicosis it has now been wholly superseded by radioactive iodine

Radioactive iodine introduced as a potent therapeutic agent by Hertz and Roberts (1942 1946) has fulfilled its early promise (Chapman 1948 Prinzmetal *et al* 1949 Moe *et al* 1950) Until a sufficient number of patients have lived 20 years after the irradiation the risk of subsequent carcinoma cannot be accurately assessed In the meantime all workers are disinclined to advocate it in patients under 45 years of age with a life expectancy of at least 20 years In older patients in subjects with other diseases that have a relatively poor prognosis such as V D H or ischæmic heart disease when thyroidectomy is refused or considered too dangerous or when thyrotoxicosis has recurred post operatively radioactive iodine is the treatment of choice An absolute contra indication however, is pregnancy for the fœtal thyroid may concentrate I^{131} and be destroyed or seriously damaged

The therapeutic dose of I^{131} is approximately 100 to 200 microcuries per gram of estimated thyroid mass the exact dose depending upon the degree to which the gland concentrates radioactive iodine and the duration of its activity in the gland (Blomfield *et al* 1951)

The results of so treating 140 patients were reviewed after one year by Blomfield *et al* (1955) Symptoms usually abated within three to six months and finally 84 per cent became euthyroid myxœdema developed in 12 per cent and 4 per cent remained thyrotoxic There were no deaths

The thyroid gland usually became smaller in size and exophthalmos did not increase in the series reviewed (but may do so occasionally) The only side effect was rheumatism which occurred four to eight weeks after treatment in about 10 per cent of cases half of them non articular and recovering spontaneously

These results are impressive and certainly suggest that radioactive iodine would be the treatment of choice in all cases of thyrotoxicosis if the risk of subsequent carcinoma proves to be less than 2 per cent

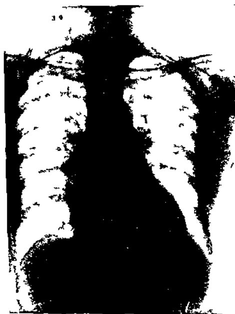
Thyrotoxic crises Owing to the impossibility of neutralising thyroid hormone that has already been manufactured both iodine and thiouracil do not benefit the patient for several days (graphs illustrating the effect of partial thyroidectomy iodine and thiouracil on the basal metabolic rate are remarkably similar) The treatment of thyrotoxic crises by massive doses of iodine (by mouth or intravenously) as advocated by Boland and Kepler (1938) for example is therefore questionable Absolute rest heavy sedation and replacement of salt and water lost in sweating and vomiting are probably more important Aneurin, 100 mg. intravenously may also help

If toxic goitre is recognised and treated promptly however crises should not occur

Thyrotoxicosis and tonsillitis Cases are encountered in which an attack or repeated attacks of tonsillitis are associated with thyrotoxicosis The problem then arises whether to perform partial thyroidectomy or tonsillectomy first Before the introduction of thiouracil most authorities agreed that it was safer to remove the thyroid gland before the tonsils for tonsillectomy in thyrotoxic patients sometimes precipitated a crisis Thiouracil has simplified the problem however and allows tonsillectomy to be undertaken first without risk

Fig 20 08—Skiagram showing gross cardiac enlargement in a case of thyrotoxicosis plus mitral stenosis

Thyrotoxicosis and rheumatic heart disease Thyrotoxicosis may be associated with acute rheumatic carditis or with established rheumatic valve lesions Both Parry's and Basedow's first cases were so related The association if more than a coincidence is indirect and may depend upon their joint relationship to streptococcal tonsillitis Rheumatic heart dis



ease with fixed valve lesions may result in enormous enlargement of the heart owing to the excessive work induced by thyrotoxicosis (fig 20 08) and the sooner the latter is treated the better Radioactive iodine is ideal for these cases

Thyrotoxicosis and hypertension There is a group of cases sometimes designated thyrotoxic hypertension in which thyrotoxicosis is associated with high blood pressure both systolic and diastolic levels being raised There is little evidence of any direct relationship between the two diseases and the blood pressure does not fall following thyroidectomy (Bisgard 1939)

Thyrotoxicosis and angina pectoris Ischæmic heart pain occurs when the blood supply to the myocardium is insufficient to meet the demand By increasing the demand thyrotoxicosis may induce angina in a patient with

Fig 20 09 (a)—Thyrotoxic heart failure

(b)—After subtotal thyroidectomy

a relatively minor degree of coronary atherosclerosis behaving in this respect like anæmia Thyroid hormone also sensitises the organism to adrenalin When ischæmic and thyrotoxic heart disease are associated angina may be completely relieved at least temporarily by successful treatment of the thyrotoxicosis preferably by means of radioactive iodine

Thyrotoxicosis and pregnancy Thyrotoxicosis developing during pregnancy may be due to primary exophthalmic or nodular goitre With the aid of thiouracil in combination with small doses of iodine or thyroid patients should be taken safely to term If the condition does not then subside subtotal thyroidectomy may be carried out The danger of goitre

developing in the fœtus is minimised by the iodine (or thyroid) but it is well to keep the dose of antithyroid drug as small as possible

PROGNOSIS

There are few forms of heart disease that respond better to adequate treatment than thyrotoxic heart disease Cases with gross congestive failure and well established auricular fibrillation may be cured and the largest hearts may resume their normal size (fig 20 09) On the other hand heart failure and death are inevitable if the disease remains unchecked In the hands of the best surgeons the mortality rate of subtotal thyroidectomy in cases of toxic nodular goitre has been 1 6 per cent (Cole 1944) to 2 6 per cent (Dunhill 1937) but it may be less with thiouracil preparation No reliable figures are available upon which to assess the total relapse rate Post operative tetany and paralysis of the vocal cord each occurs in approximately 1 per cent (Means 1946)

Myxœdema which may follow otherwise successful treatment of thyrotoxicosis however accomplished is easily controlled by a maintenance dose of thyroid gr 3 or L thyroxine sodium 0 3 mg daily

THE HEART IN MYXŒDEMA

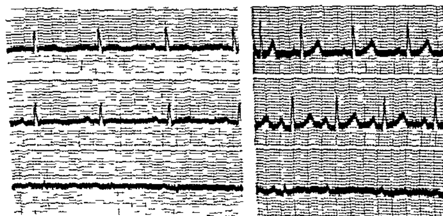
Artificial myxœdema produced by total ablation of the thyroid gland or by antithyroid drugs benefits the heart by lessening the circulatory demands and so relieves angina pectoris and congestive heart failure Yet well developed myxœdema from natural causes gives rise to cardiac enlargement pericardial effusion and ultimately to congestive heart failure moreover angina pectoris may be associated Enlargement cannot be due to overwork it must depend upon some intrinsic change in the heart muscle Histological examination however, is usually disappointing The fault is probably biochemical and is unlikely to be properly understood until studies in tissue chemistry are more advanced

The diagnosis of myxœdema is suggested by the placid sleepy character (unless there is manic psychosis) poor memory sensitivity to cold (Raynaud s phenomenon is common) dry coarse skin thickened lips and tongue low thick voice baggy eyes scanty dry hair podgy hands supraclavicular pads of fat and general pallor It is confirmed by an impalpable thyroid gland by a B M R of minus 30 to 40 per cent by prolongation of the arm to tongue circulation time to 19 to 25 seconds by a high blood cholesterol of 300 to 400 mg per cent by relative insensitivity to atropine and adrenaline by a characteristic form of anæmia and by a pathognomonic electrocardiogram If further proof is needed it may be obtained by demonstrating failure of the thyroid gland to extract radioactive iodine after a test dose so that the neck thigh ratio remains unaltered (Foote *et al* 1957) a thyroid clearance of only 1 to 4 ml per minute (Pochin 1950) or an abnormally high urinary excretion of radio iodine (Mason 1949 Fraser *et al*, 1953) Estimation of the protein bound radiothyroxine 48 hours

after a test dose of I^{131} does not distinguish myxœdema from normal controls (Wayne 1954)

The type of anæmia that responds to thyroxine alone is normocytic and orthochromic, and may be regarded as a compensatory adjustment to diminished oxygen requirement (Bomford 1938) The electrocardiogram shows sinus bradycardia low voltage atrial and ventricular complexes and flat or inverted T waves in all leads (fig 20 10) The cause of these changes is not yet understood they do not depend upon the presence of pericardial effusion nor upon the state of the subcutaneous tissues The response to thyroxine is quick and complete and accompanies beneficial changes in the B M R The electrocardiogram in cretinism behaves similarly (fig 20 11) (Schlesinger and Landtman 1949)

Whilst a well developed case of myxœdema is difficult to overlook (fig 20 12) cases of short duration especially in younger women (the sex incidence is 8 1 in favour of women) may easily escape notice The diagnosis should be considered in any case of congestive heart failure or of peri-



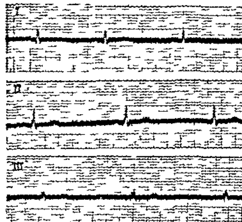


Fig 20 10 (a)—Electrocardiogram showing sinus bradycardia low voltage atrial and ventricular complexes and flat T waves in all leads in a case of myxœdema
(b) Normal electrocardiogram after treatment

cardial effusion of unknown etiology Congestion when it occurs is systemic and is associated with a low cardiac output Pericardial effusion is due to simple transudation Cardiac enlargement is general and pulsation of all chambers poor Angina pectoris has been said to occur in only 1 to 2 per cent of cases (Smyth 1938), but is surely much more frequent (Hueper 1944 1945) Coronary atherosclerosis may result from the high blood cholesterol Myocardial infarction without coronary thrombosis has been described in such cases when treated too vigorously with thyroxine The blood pressure is little influenced by myxœdema and is as often elevated as low When congestive failure is present measurements of the B M R give unduly high readings more reliance should then be on other tests, especially on the electrocardiogram

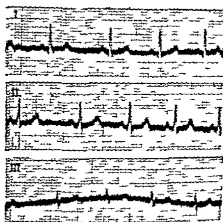

Fig 20 11—Electrocardiogram before and after trea ment in a case of cretini m

Fig 20 12 (a)—Myxœdema

(b) After seven weeks treatment.

Treatment If there is no evidence of coronary disease thyroxine may be given intravenously in a single dose of 10 mg or thyroid may be given by mouth in doses of 3 grains (0 2 G) daily The response is delayed but dramatic Within five to ten days the B M R rises the blood cholesterol falls the T wave begins to change and clinical improvement is obvious Signs of failure or of pericardial effusion soon disappear and the heart gradually resumes its normal size (Lerman Clark and Means 1933)

Initial treatment is easier than maintenance With the aid of the B M R it is not difficult to regulate dosage for a patient at rest in bed but when she leaves hospital and varies her activities it is not so easy and supervision is required for life The average maintenance dose of thyroid is 3 grains (0 2 G) daily by mouth or 0 3 mg of L thyroxine sodium

If there is any suspicion of associated coronary disease initial treatment should be cautious and the oral route advised Not more than 1 grain (65 mg) of thyroid should be given daily and in cases with angina pectoris not more than ½ a grain (32 mg) The dose may be increased slowly week by week if well tolerated or reduced and maintained at a minimum if not tolerated

The chief complication arising during treatment is the development of angina pectoris should this occur the dose of thyroid may have to be less than ideal but enough to keep the blood cholesterol below 300 mg per cent

CHAPTER XXI

HYPERKINETIC CIRCULATORY STATES

(ANÆMIA PREGNANCY ARTERIO VENOUS FISTULA, BERI BERI PAGET S DISEASE OF BONE HEPATIC FAILURE)

IN addition to the diseases enumerated above hyperkinetic circulatory states (Harrison 1935) include thyrotoxicosis anoxic cor pulmonale fever and exercise The first two have been considered fully elsewhere and the last two have a purely physiological basis

All these conditions are characterised by a raised cardiac output maintained by means of tachycardia a raised venous filling pressure or both moreover the heart may beat more strongly Conspicuous evidence of vaso dilatation in skin and muscle is found in all of them the skin is warm and flushed the forearm veins are distended the pulse is bounding the digital vessels throb and there may be capillary pulsation The forearm and calf blood flows are increased Whilst young and healthy hearts may cope with the situation without distress older or unhealthy hearts may fail to meet the requirements The chief symptoms are palpitations and breathlessness

It may be difficult clinically to recognise congestive failure in these cases for the usual signs may have other interpretations Thus a raised venous pressure may be part of the physiological mechanism maintaining a high cardiac output (McMichael 1947) enlargement of the liver may be due to secondary carcinoma or to hepatitis and œdema is commonplace in severe anæmia and beri beri for other reasons Indeed it is by no means easy to be sure what is meant by failure in this group for example McMichael uses the term high output failure to describe a state in which a raised venous pressure and œdema are associated with a high cardiac output whether or not the latter is capable of being raised further Yet failure ordinarily denotes an overloaded heart or ventricle one incapable of raising its output further But this question has already been discussed (page 264)

THE HEART IN ANÆMIA

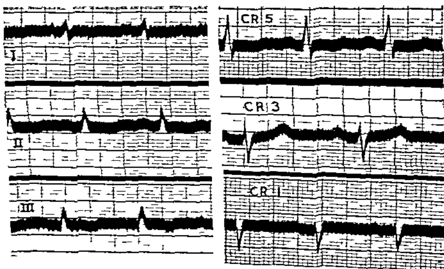
Physiology Severe chronic or post hæmorrhagic anæmia may affect the heart in three ways (i) it may cause a hyperkinetic circulatory state as described above (ii) it may cause or precipitate angina pectoris or acute coronary insufficiency (iii) it may result in nutritional degenerative changes in the cardiac muscle which may reduce its reserve

With an oxygen consumption of 240 ml per minute an anæmic subject with a hæmoglobin of 20 per cent could not have a cardiac output less th

6 litres per minute if all the available oxygen were utilised (20 per cent Hb = 3 G Hb per cent = 3 × 1 34 ml oxygen per cent = 4 ml oxygen per cent or 40 ml per litre Thus cardiac output = $\frac{240}{40}$ = 6 litres per minute) If half the available oxygen were utilised the cardiac output would be 1 litres per minute

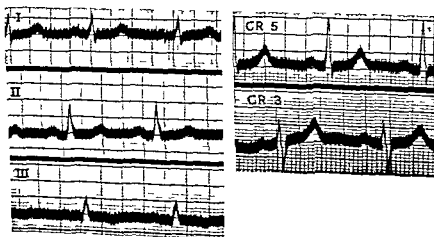
In anæmic subjects investigations have shown that the resting cardiac output may reach 13 litres per minute and utilisation of available oxygen may be increased from the normal 33 per cent to as much as 90 per cent (Liljestrand and Stenstrom 1925–6 Nielson 1934 Sharpey Schafer 1944) These changes do not occur at rest with hæmoglobin values above 50 per cent but become increasingly apparent at lower levels (Bouchut and Froment 1934) The high cardiac output is maintained both by tachycardia and a raised venous pressure The latter must be due to widespread capillary or peripheral venoconstriction for the blood volume is reduced (McMichael *et al* 1943) and the small arteries and arterioles are dilated (McMichael 1947)

Clinical features The chief symptoms of severe anæmia are breathlessness fatigue and palpitations Angina pectoris occurs in about 30 per cent (Coombs 1926 Pickering and Wayne 1934) occasionally even when there is no underlying coronary disease Thus the author has treated a boy of 17 with pernicious anæmia and angina pectoris and also a young man of 21 who presented himself with classical ischæmic heart pain due to iron deficiency anæmia resulting from bleeding hæmorrhoids Œdema may be due to congestive heart failure but is more often nutritional It is especially prone to develop during the first three weeks of blood regeneration in response to treatment of the anæmia



Paroxysmal cardiac dyspnœa or acute pulmonary œdema is rare as a spontaneous event but may arise during blood transfusion or saline infusion These procedures should not be lightly undertaken in cases of severe chronic or post hæmorrhagic anæmia precautionary measures include the use of concentrated red cells instead of whole blood and venous pressure lowering agents such as cuffs applied to the thighs Transfusion should be temporarily abandoned if the venous pressure is seen to rise appreciably

Physical signs A hyperkinetic circulation and peripheral vasodilatation may be recognised by the features detailed previously



A functional systolic murmur (so called hæmic murmur) at apex or base is common and is due to the increased blood flow through the aortic and pulmonary valves Functional mitral or aortic diastolic murmurs may also be heard occasionally earlier observations such as those by Von Noorden (1891) Sahli (1895) and Kraus (1905) having been amply and repeatedly confirmed (Goldstein and Boas 1927) Mitral presystolic or diastolic murmurs are probably due directly or indirectly to the increased velocity of blood flow the mechanism being the same as that responsible for mitral

diastolic murmurs in patent ductus arteriosus ventricular septal defect and thyrotoxicosis Basal diastolic murmurs are attributed to dilatation of the aortic or pulmonary ring

The electrocardiogram Despite several publications emphasising the normality of the electrocardiogram in anæmia (e g Smith 1933 Pickering and Wayne 1934) there can be no doubt that significant changes occur in at least a third of cases with hæmoglobin values under 40 per cent (Block, 1937) In a consecutive series of twenty such cases analysed by the author

(a) Before treatment

(b) After treatment of the anæmia

Fig 21 03—Skiagram showing general cardiac enlargement in a case of severe pernicious anæmia

eight showed low voltage depressed S T segments or flat or inverted T waves in left ventricular surface leads or their equivalents As the anæmia improved under treatment these faults were corrected (fig 21 01) Several instances of bundle branch block have also been observed but these have always persisted when the anæmia was cured Depression of the S T segment is common following gross hæmorrhage and is believed to represent temporary coronary insufficiency (fig 21 02)

Fluoroscopy X rays often reveal slight enlargement of all chambers of the heart and prominence of both the aorta and pulmonary artery in cases with hæmoglobin levels below 40 per cent (fig 21 03)

Necropsy studies have revealed slight increase of heart weight (350 to 450 G) in the majority of cases of severe anæmia and considerable increase occasionally (Cabot and Richardson 1919) Experimental anæmia in rats has resulted in slight cardiac hypertrophy at hæmoglobin levels of 10 G per cent and considerable hypertrophy (weight at least twice normal) at levels of 2 to 3 G per cent (Forman and Daniels 1930–1) According to Grunberg (1930) hypertrophy is invariable in man when the hæmoglobin is 15 per cent or less and does not occur at all when the hæmoglobin is 66 per cent or more

These findings harmonise with the behaviour of the cardiac output in relation to hæmoglobin levels and there can be little doubt that enlargement depends on increased work

Clinical diagnosis Knowledge of cardiovascular behaviour is of little value in making a diagnosis of anæmia and is of no value at all in determining the nature of the anæmia It is helpful however in differential diagnosis especially between anæmia the anxiety states and bacterial endocarditis Thus an anxiety state may present with the same group of symptoms including pallor and there may be cardiac over action and functional systolic murmurs The pallor however, is due to peripheral vasoconstriction and does not affect the conjunctivæ or the mucous membranes and it is less obvious in the palms of the hands the nail beds too are more likely to be cyanosed than pale In anæmia pallor is often waxy chalky or lemon tinted according to its severity and type The cardiovascular dynamics are quite different Over action of the heart and tachycardia in the anxiety states are associated with little or no rise in cardiac output there is peripheral vasoconstriction rather than vasodilatation and the diastolic blood pressure tends to be raised in casual readings the stroke volume tends to be reduced and the pulse may be small the circulation time and venous pressure are normal There are however exceptions to this general pattern about 10 per cent of patients with an anxiety state having a hyperkinetic circulation probably caused by an excess of circulating adrenaline

A type of case that may cause confusion is one that presents with pallor low grade fever petechiæ splenomegaly over action of the heart and a loud systolic murmur at apex or base Bacterial endocarditis may be sus

pected especially when there is a diastolic basal murmur as well and the pulse is collapsing yet all these features may be due to anæmia alone

Treatment All cardiovascular changes due to anæmia are reversible if the anæmia is treated successfully Cardiac remedies are rarely required apart from urgent measures in the event of acute pulmonary œdema The danger of ill judged or too rapid intravenous infusion has already been mentioned

THE HEART IN PREGNANCY

PHYSIOLOGY

There is now sufficient evidence to state with confidence that the hyper kinetic circulation of pregnancy begins to develop during the *second month* is well established by the end of the third month, increases slightly and gradually to the thirty second week and thereafter declines Much of this evidence has been summarised by Morgan Jones (1951)

Clinically the palms flush the extremities are hot the digital vessels throb capillary pulsation may be demonstrated the pulse is full and bounding the heart rate quickens the venous pressure rises the soft tissues become more tense and there may be slight œdema The heart itself is hyperdynamic the cardiac impulse is forcible and displaced slightly to the left aortic and pulmonary systolic murmurs heard at apex and base advertise the increased blood flow a loud third sound confirms rapid ventricular filling and X rays may reveal slight diastolic enlargement Ectopic beats are common The electrocardiogram often shows a prominent S wave in lead I and a conspicuous Q wave and inverted T wave in lead III (fig 21 04) *due to rotation of the heart*

Special tests reveal the following

(1) Oxygen consumption is increased by 15 to 20 per cent (Burwell 1937 1938)

(2) The cardiac output increases by 50 per cent (Palmer and Walker 1949 Hamilton 1949)

(3) Retention of sodium and water results in considerable hæmodilution *the increase of plasma volume reaching a maximum of 45 per cent above normal by the thirty second week* (Cohen and Thomson 1936 Thomson *et al* 1938) after which diuresis sets in (Chesley 1943)

(4) The general venous pressure rises as a result of the increased blood volume sometimes considerably the venous *pressure in the legs* is particularly high owing to the local obstructing effect of the enlarged uterus (Burwell *et al* 1938) Compression of the inferior vena cava is common in the supine position and the fall in right atrial pressure and cardiac output that may result from pooling of blood in the legs may cause faint ness and seriously interfere with physiological studies

The circulatory effects of pregnancy are attributed chiefly to the in

creased blood volume whilst the rise in oxygen consumption and a uterine arterio venous shunt (Burwell 1938) are contributory

Whilst the normal heart tolerates the added load easily enough diseased hearts may not When trouble occurs it usually *begins* early often by the end of the third month The *onset* of heart failure proper occurs with increasing frequency up to the end of the thirty second week after which it steadily declines (Hamilton and Thomson 1942)

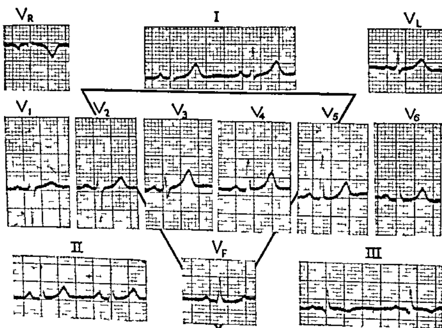

Fig 21 04—Electrocardiogram showing characteristic appearances associated with pregnancy

Frequency and types of heart disease associated with pregnancy

Heart disease was recognised in 1 3 per cent of 80 422 pregnant women analysed by Haig and Gilchrist (1949) Of their 1 100 heart cases 94 per cent were rheumatic 3 6 per cent congenital 1 8 per cent hypertensive and 0 6 per cent miscellaneous Similar figures (see table) have been published by Hamilton (1935) Morgan Jones (1951) and many others

Hypertension associated with toxæmia of pregnancy is obviously excluded from these statistics since this occurs in 5 per cent of all pregnancies Toxæmia is particularly dangerous in cases of heart disease not because of the hypertension (except in relatively rare cases of hypertensive heart disease) but because of the sodium and water retention

The mortality from heart disease in pregnancy averages 4 5 per cent (Jensen 1938 Jones 1951) but naturally varies greatly according to the

NO OF PREGNANT WOMEN WITH HEART DISEASE	NATURE OF HEART DISEASE (frequency per cent)				AUTHORS
	RHEUMATIC	CONGENITAL	HYPER TENSIVE	MISC	
1 335	93	5 2	—	1 8	Hamilton (1935)
1 100	94	3 6	1 8	0 6	Haig and Gilchrist (1949)
485	90	6 8	1	1 1	Morgan Jones (1951)

severity of the lesion If patients are classified according to their grade of previous effort intolerance as defined on page 521 then the mortality from heart disease increases from about 0 4 per cent in grades 0 to 2A 5 3 per cent in grade 2B and 22 6 per cent in grades 3 and 4 (Jensen 1938) These figures were based on 1,428 cases collected from the literature over 90 per cent of them rheumatic Hamilton (1947) reported somewhat similar figures in a series of 1 335 cases of heart disease in pregnancy (93 per cent rheumatic) the mortality in grades 0 to 2A was 2 per cent as it was in non pregnant controls with heart disease of similar degree whereas in grades 2B to 4 the mortality was 18 per cent, compared with 6 7 per cent in non pregnant controls When there was atrial fibrillation the maternal mortality was 32 per cent (8 per cent in non pregnant controls)

Infant mortality should also be considered In Hamilton s series this was 8 6 per cent in the favourable group 31 per cent in the unfavourable group and 50 per cent when there was atrial fibrillation

Figure 21 05 which has been constructed from data published by Jensen (1938) shows that mortality increases steadily throughout pregnancy and reaches its climax during labour itself and the ensuing 24 hours

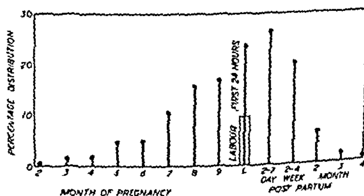

Fig 21 05—Chart showing when death occurs in fatal cases of heart disease associated with pregnancy

nearly 24 per cent of the 462 deaths analysed occurring at this time but the puerperium is also dangerous 26 per cent of the deaths occurring between the second and seventh day after delivery and 20 per cent during the next fortnight Werko (1954) regards the first 48 hours after delivery as the most dangerous period

The commonest causes of death are congestive heart failure (36 per cent) and pulmonary œdema (27 5 per cent) (Jensen 1938) The latter is chiefly responsible for death during pregnancy, the former for death during or after delivery (Morgan Jones 1951)

General Management

Irrespective of the type of heart disease present the following general rules are widely accepted

1 Patients with grade 0 to 1 effort intolerance should not ordinarily be dissuaded from having a family and should experience little extra trouble during pregnancy and the puerperium

2 Patients with grade 2B to 4 effort intolerance who cannot be radically improved by present methods of treatment should be advised not to have a family and pregnancy should be terminated within the first three months if already present If the nature of the cardiac lesion is beyond foreseeable therapeutic developments sterilisation should also be carried out but not otherwise If the pregnancy is already advanced it is usually best to allow it to continue to its natural conclusion

3 Patients with grade 2A effort intolerance should be considered individually and social factors may be taken into account

4 If the cardiac lesion calls for surgical treatment the operation is best undertaken before pregnancy if the patient is already pregnant the operation should be carried out without delay if effort intolerance is grade 2B or more or deferred for a year or so if effort intolerance is grade 0 to 2A The pregnancy itself should not be terminated and sterilisation is unjustified

5 The best means of combating the adverse effect of pregnancy on the cardiovascular system is the low sodium diet supported if necessary by mercurial diuretics mictine diamox or resins Digitalis is not indicated when pulmonary œdema is due to mitral stenosis but is helpful in cases of atrial fibrillation and congestive heart failure Prolonged rest preferably in bed should be enforced until the situation is well in control

RHEUMATIC HEART DISEASE AND PREGNANCY

There are some who maintain that any woman who has rheumatic heart disease should be advised against having any children They argue that pregnancy affects her adversely and that the strain of bringing up children shortens her life Others feel that to forfeit so much human happiness on these grounds is both undesirable and unnecessary Is life so precious to

prolong if so much of its meaning is taken away? Moreover available statistics barely support the first argument Thus in four combined series collected by Jensen (1938) the average age of death in spinsters or nulliparous women with mitral stenosis was 36 6 in married women with families it was 40 3 Again, Bunim and Rubricius (1948) could find no significant difference in the life histories of 169 rheumatic mothers and 215 rheumatic childless women Of course, the childless women may have been advised against pregnancy owing to the severity of their condition so that the two groups may not be strictly comparable there is insufficient evidence on this point It is certain however that many women with mitral stenosis unaware that there is anything wrong with them have large families and lead normal lives until the lesion is discovered in later life

Over 90 per cent of all cases of heart disease associated with pregnancy are rheumatic and at least four fifths of these have mitral valve disease usually stenosis The increased blood volume and raised cardiac output result in further elevation of the left atrial pressure and since the rapidity of the change leaves little time for the development of physiologically protective mechanisms hæmoptysis and acute pulmonary œdema are relatively common Less frequently and chiefly in those with a high pulmonary vascular resistance uncontrolled atrial fibrillation myocardial fibrosis or active rheumatic carditis the extra load results in congestive heart failure Pulmonary embolism increases the mortality during the puerperium

The majority of patients with uncomplicated mitral stenosis who experience serious trouble during pregnancy *begin to develop symptoms of* increasing pulmonary congestion towards the end of the third month conversely if all is well at the end of the first trimester without prophylactic treatment little trouble is likely to arise later Clinically when assessing the physiological situation due allowance must be made for the fact that 60 per cent of normal women experience breathlessness during pregnancy (Hamilton and Thomson 1942) and that a slight rise of venous pressure is normal

When considering the question of future pregnancy in cases of rheumatic heart disease it is vitally *important to make sure* whether surgical treatment is possible or not In cases of *aortic or mitral incompetence* for example pregnancy should be avoided or terminated within the first few months if effort intolerance is grade 2A or more for these lesions cannot yet be corrected surgically and any deterioration may well prove disastrous moreover both aortic and mitral incompetence must be advanced before grade 2 effort intolerance develops

Cases of mitral stenosis on the other hand are relatively safe if symptoms are already moderate or severe, valvotomy should be carried out before pregnancy if effort intolerance is only grade 1 to 2A and the pulmonary vascular resistance normal valvotomy should *be deferred and pregnancy* allowed to take its natural course if serious symptoms then develop

valvotomy may be performed during pregnancy which need not be terminated Cases of mitral stenosis with a raised pulmonary vascular resistance require valvotomy before pregnancy irrespective of the grade of effort intolerance for they are likely to develop congestive heart failure late in pregnancy or during the puerperium with or without pulmonary embolism When the patient is already pregnant valvotomy should be performed as soon as possible and if the operation is technically successful the pregnancy should be allowed to continue

Although *rheumatic aortic stenosis* may be relieved surgically the high mortality and relatively indifferent results of the present operation are not reassuring and patients with this lesion should be managed in respect of pregnancy like patients with aortic incompetence

Previous statistics showing no difference in the mortality rate from mitral stenosis and the other valve lesions in relation to pregnancy do not apply now that mitral stenosis can be relieved surgically

Normal pregnancy is safe after technically successful valvotomy in cases with previous mitral stenosis but toxæmia can be very dangerous when there is mild residual stenosis pulmonary œdema then occurring very readily One of the writer s post operative cases died under just these circumstances and necropsy revealed a partially split valve with an orifice measuring approximately 2 5 × 1 cm

Retention of sodium and water must be countered strenuously with a rigid low sodium regime

Cases of active rheumatic carditis are probably best terminated as soon as the state of the heart permits for there is no knowing what the sub sequent course will be and a relapse later in pregnancy may prove very serious

When pregnancy is not advised prevention is best insured by a simple sterilising operation Termination of pregnancy is by therapeutic abortion in the first three months by abdominal hysterotomy from the fourth to the sixth month by induced labour or by Cæsarean section during the seventh and eighth months by natural means or by Cæsarean section at term The choice must rest with the obstetrician

CONGENITAL HEART DISEASE

Any form of congenital heart disease compatible with adult life may obviously be associated with pregnancy *In practice* the more common lesions include atrial septal defect patent ductus arteriosus pulmonary stenosis with normal aortic root coarctation of the aorta ventricular septal defect and Fallot s tetralogy—in that order of frequency With the exception of ventricular septal defect all these lesions can now be repaired or relieved surgically and if severe enough to warrant such treatment the operation should be carried out before pregnancy If the patient is already pregnant surgical treatment should not be delayed and the pregnancy need not then be terminated Patients who have had severe congenital heart

disease cured repaired or sufficiently relieved surgically may have one or more babies subsequently without ill effect Mild congenital lesions are no bar to pregnancy and do not adversely influence obstetrical mortality

Atrial septal defect of mild or moderate degree is compatible with many normal pregnancies If severe however it should be repaired with the aid of hypothermia, preferably before, but if necessary during the early months of pregnancy

Patent ductus arteriosus is now treated surgically as a routine however mild If a small duct is discovered for the first time during pregnancy it is better to defer operative treatment but ducts of moderate or large size are better ligated without delay

Severe pulmonary stenosis has been relieved during pregnancy on several occasions and patients operated on previously have had normal pregnancies subsequently The second statement also applies to cases of Fallot's tetralogy who have been successfully relieved by pulmonary valvotomy or infundibular resection

Coarctation of the aorta may be discovered for the first time during pregnancy on account of the hypertension Although the majority of cases go through to term safely a few end disastrously with rupture of the aorta and to avoid this risk surgical repair is probably best undertaken at once if the condition is diagnosed within the first three months If not recognised until later however it may be better to defer the operation and to allow the pregnancy to proceed delivering the baby by means of Caesarian section to avoid the risk of vascular accidents during labour (Benham 1949)

Since *ventricular septal defect* cannot yet be repaired satisfactorily severe cases should avoid pregnancy or should have the pregnancy terminated in the early months Cases of mild or moderate severity run no special risk Sterilisation is not justified because successful surgical repair may soon be possible

BACTERIAL ENDOCARDITIS

Before the introduction of penicillin the life of the fœtus was the main consideration The situation is now reversed however and every effort should be made to save the mother As heart failure is now the chief cause of death from bacterial endocarditis, termination of pregnancy may often be desirable

THYROTOXICOSIS

One of the few known factors that may aggravate or precipitate thyrotoxicosis is pregnancy It follows that thyrotoxic women should be advised against pregnancy until they are cured Improvement on rest and iodine or as a result of thiouracil treatment is not enough such cases tend to relapse during pregnancy At least a year should pass after partial thyroidectomy or thiouracil cure before conception should be considered

If a woman is thyrotoxic and already pregnant therapeutic abortion should be considered during the first three months if not seen until gestation is more advanced it may be wiser to take the patient to term with the aid of thiouracil Subtotal thyroidectomy is better deferred owing to the risk of relapse The dose of thiouracil must be the minimum that is effective for there is some danger of its causing goitre in the fœtus the simultaneous administration of small doses of iodine or thyroid may prevent this

HYPERTENSION

High blood pressure discovered during pregnancy may be due to chronic persistent hypertension (usually essential) or to toxæmia of pregnancy Essential hypertension may be aggravated by pregnancy but with rest diet and sedatives mild cases can be taken to term Nevertheless women with high basal blood pressures (above 160/100 mm Hg) should be advised against pregnancy in view of the increased risk of toxæmia the high infant mortality (66 per cent according to Browne 1947) and the chances of serious aggravation For similar reasons pregnancy should be terminated in women with relatively high pressures in the first three months Hypertension associated with toxæmia of pregnancy is a separate problem and will not be considered here

ARTERIO VENOUS FISTULA

Arterio venous fistula may be congenital (circoid aneurysm) or acquired (usually as a result of a perforating wound) and may occur in any situation particularly in the brain limbs or lung

Physiology

Experimentally an artificial arterio venous fistula between the femoral artery and vein for example results in an immediate fall of blood pressure slight elevation of the venous pressure acceleration of the pulse and rise of cardiac output whilst locally the distal part of the leg becomes œdematous the skin cold and the toes occasionally gangrenous (Holman 1937) Physiologically the fistula acts as a zone of low resistance in the arterial circulation The drop in blood pressure is due to the fall in total peripheral resistance the greatly increased blood flow through the fistula tends to raise the venous pressure the tachycardia is due to the fall in blood pressure acting on carotid and aortic baroreceptors the rise in venous pressure usually being too slight to stimulate the Bainbridge reflex the increased cardiac output is due to a combination of the fall in total peripheral resistance which encourages the heart to empty itself more completely the slight rise of venous filling pressure and the tachycardia Locally œdema of the leg has been attributed to great elevation of the femoral venous pressure coldness pallor and gangrene to a diminished blood flow distal to the lesion for it is much easier for blood to pass through the fistula than through the normal channels (Holman 1937)

After a variable time several important changes take place The blood volume increases and raises the venous pressure more conspicuously the cardiac output is thus augmented and the blood pressure gradually restored The shunt through the fistula is increased by these changes but sooner or later a state of balance is reached Locally, the vessels carrying the shunt become dilated even aneurysmal the artery below the fistula is affected as well as that above, because blood entering the distal part of the terminal artery from collateral channels is forced backwards by the peripheral resistance to the fistulous zone of lower resistance The dilated arteries that accommodate the increased flow become thin walled and the veins receiving the flow at a higher pressure than that to which they are accustomed become arterialised in other words both become anatomically adjusted to the new pressure With the increased blood volume and total cardiac output the blood flow to the distal part of the leg is not only restored but often becomes greater than normal The leg becomes hot and the veins distended and when initial œdema has subsided the leg usually remains larger than its fellow (Holman 1937)

The physiology of congenital and acquired arteriovenous fistula is the same as that found experimentally both in the initial and later stages of development Local effects were well described by Reid (1925) amongst others and Cohen *et al* (1948) confirmed that the blood flow in the affected limb distal to the fistula was diminished in early cases and increased in cases of long duration The increased blood volume was demonstrated by Rowntree and Brown (1929) and the raised cardiac output by Warren *et al* (1947) and Cohen *et al* (1948) In congenital cases the increased vascularity of ununited epiphyses in the affected limb may lead to considerable hypertrophy of one arm or leg (Horton 1932)

CONGENITAL CIRCOID ANEURYSM

Circoid aneurysm consists of a twisted mass of dilated vessels in which artery and vein are in direct communication One or more superficial hæmangiomas may be seen elsewhere or there may be a family history of such nævi

The cerebral type may give rise to epilepsy subarachnoid hæmorrhage or ophthalmoplegic migraine Examination may reveal a systolic murmur heard best through the eye ball on the affected side or sometimes over the skull The diagnosis may be proved by finding an unduly high oxygen saturation in samples of blood obtained from the ipsilateral jugular vein The lesion may be localised by means of angiography 10 to 20 ml of 70 per cent diodone or other radio opaque substance being injected rapidly into the carotid artery and skiagrams of the cerebral vessels being obtained at the appropriate moment The condition should be distinguished from berry aneurysm and from Sturge s disease *in* which facial and pial nævi without arterio venous communications are associated with calcification of brain substance epilepsy mental retardation and glaucoma (Nussey) and

Fig 21 06 (a)—Skiagram showing a congenital arterio venous aneurysm of the lung The appearances bear some resemblance to those of pulmonary tuberculosis
(b) Angiocardiogram showing diodone filling the aneurysm

A k owl dgment t Dr Cl l B k

Miller 1939) Treatment consists of ligation of the common carotid artery on the side of the lesion if after trial compression hemiplegia or other serious ischæmic symptoms do not occur The risk of such an untoward event increases progressively with the age of the patient

Circoid aneurysm in a limb presents similar features to those of its traumatic cousin It may be situated anywhere from the shoulder or pelvic girdle to the hand or foot There is usually an increase in blood flow to the limb which may be longer and larger than its fellow Occasionally however there is ischæmic atrophy in one or more digits distal to an aneurysm in the hand or foot The veins stand out are sometimes varicose and may exhibit arterial pulsation and the skin temperature is raised It may be possible to locate the aneurysm with precision by observing the effect on the local and general circulation of compressing the various arteries of the limb at appropriate points An impressive machinery murmur and thrill may be appreciated over the fistula itself Venous blood from the affected limb may be more saturated with oxygen than venous blood from the unaffected limb The exact location and construction of the aneurysm may be demonstrated by means of angiography Treatment is more difficult than in traumatic cases Excision is usually impossible owing to the diffuse nature of the lesion moreover affected vessels are physiologically abnormal and fail to constrict when injured so that severe and

prolonged hæmorrhage may follow surgical interference Ligation of the main vessels leading to the aneurysm (above and below) may be possible but deep X-ray therapy is usually best

Congenital arterio venous aneurysm in the lung, which is associated with telangiectasis elsewhere in 50 per cent of cases (Baer *et al* 1950), causes venous blood from the pulmonary artery to be shunted directly into the pulmonary veins and thence into the arterial circulation, at the same time the blood flow through the rest of the lung may be reduced the steep pressure gradient through the aneurysm offering the easier pathway The result is a lowered arterial oxygen saturation in the region of 70 to 75 per cent (Burchell and Clagett 1947) central cyanosis polycythæmia and clubbing Most of the cases reported have been in children or young adults Hæmoptysis has occurred in 50 per cent The heart itself is normal but there may be a continuous machinery murmur over the affected part of the lung A skiagram may show a rounded or irregular opacity (fig 21 06a) which on fluoroscopy may be seen to pulsate tomograms may reveal a dilated artery and vein in close relationship to the abnormal shadow and angiocardiograms may show the abnormal vessels filled with diodone (fig 21 06b) (Baker and Trounce 1949) Lesions may be single or multiple unilateral or bilateral Calcification may occur in the wall of an aneurysm (fig 21 07) One case (a girl aged 9) seen by the author died with cerebral abscess The condition should be distinguished from patent ductus arteriosus helping to correct pulmonary or tricuspid atresia Treatment by lobectomy or pneumonectomy is curative unless there are several widely distributed aneurysms (Barnes *et al* 1948)

Fig 21 07—Calcification in the wall of an arterio-venous aneurysm
Ack owl dgment t D Ch l B k

Congenital coronary arteriovenous fistula is very rare but is mentioned in view of its peculiar interest to cardiologists Details of a few cases that have been reported including a new one of my own are given in the accompanying table It will be noticed that four were symptom free and were detected only because of the continuous thrill and murmur When this was maximum in the third left space the fistula was between the left circumflex coronary artery and the coronary sinus when it was maximum low down

AUTHOR	AGE	SEX	SYMPTOMS	SITE OF A V MURMUR OR THRILL	E C G	X RAY	CORONARY ARTERY INVOLVED	DIAGNOSIS
Halpert (1930)	54	M	Nil	—	—	—	Right	P M
Paul *et al* (1949)	9	M	Nil	Right sternal edge 4th and 5th space	Normal	Normal	Right	Clinical and operative
Cross (quoted by Paul *et al*)	16	M	Nil	3rd and 4th left spaces	—	—	? left circumflex	Operation
Davison *et al* (1955)	58	F	Congestive heart failure	2nd 3rd 4th left spaces	A fib QRS balanced	General enlargement congested lungs	Left circumflex	P M
Wood	60	M	Nil	4th and 5th spaces right sternal edge	Normal	Calcified A V aneurysm	Right	Clinical X ray

the right sternal edge the fistula was between the right coronary artery and the coronary sinus Cardiac catheterisation was carried out in only one instance and a left to right shunt at atrial level was demonstrated the pulmonary blood flow was 6 9 litres per minute the systemic 3 1 (Davison *et al* 1955) The diagnosis could have been made had samples from the coronary sinus been obtained In my own case the diagnosis was obvious clinically and radiologically (fig 21 08) and catheterisation was not justified Of these five cases this was the only one with calcification

Fig 21 08—Calcified arterio venous fistula between the right coronary artery and coronary sinus

ACQUIRED ARTERIO VENOUS ANEURYSM

The *great majority of acquired arterio venous aneurysms* are due to perforating gunshot wounds in war and are seen most often in connexion with the femoral brachial or carotid arteries Occasionally they may be syphilitic mycotic or artificial Arterio venous shunting may also occur in highly vascular structures such as the thyroid gland in severe thyrotoxicosis or as a result of overdosage with thiouracil (page 879) the uterus in pregnancy (page 903) and the bones in active Paget s disease (page 917)

The local signs and the effect on the general circulation are *similar* to those in experimental arteriovenous fistula At first the affected limb swells the skin becomes cold and there is danger of peripheral gangrene When a state of balance is reached and compensatory adjustments have been made the œdema subsides and the limb becomes warmer than its fellow The

veins distend and may pulsate A coarse machinery murmur and thrill are invariable over the lesion itself

The general circulation is hyperkinetic and if the shunt is large enough paroxysmal cardiac dyspnœa or signs of congestive heart failure may develop as observed by Reid (1920) If the shunt is temporarily obliterated by digital compression of the femoral artery just above the lesion, the pulse rate falls 10 to 30 beats per minute (Branham's sign) the blood pressure rises 10 to 15 mm Hg the venous pressure falls slightly and the cardiac output falls (Stead and Warren, 1945) but capillary pulsation is accentuated (Lewis and Drury 1923) Slowing of the pulse is due to the rise in blood pressure and is abolished by atropine (Kramer and Kahn 1946)

Cardiac enlargement is almost certainly due to the raised cardiac output and increased stroke volume The hyperkinetic circulation is maintained by tachycardia and raised venous filling pressure whilst the peripheral resistance is further reduced by vasodilatation in skin and muscle

Treatment Any arterio venous aneurysm large enough to influence the general circulation should be repaired Smaller lesions may be left alone if causing no local symptoms and some of them become obliterated spontaneously Every effort should be made to repair the artery by lateral suture or graft so that the normal circulation is preserved (Junghann 1943) Ligation of artery and vein above and below the aneurysm is less satisfactory the resulting circulation through the brain or limb being sometimes inadequate Simple ligation of the artery above the fistula was condemned as long ago as 1886 by Bramman for this frequently results in peripheral gangrene

THE HEART AND CIRCULATION IN BERI BERI

In modern civilised communities pure beri beri is rare the clinical picture being commonly influenced by deficiencies in vitamins other than aneurin (B_1) and by associated conditions especially chronic alcoholism Aneurin (thiamine) in association with other components of the vitamin B complex is found chiefly in unpolished rice marmite liver yeast wheat and other grains It is used by the body in carbohydrate metabolism its chief known function being concerned with the oxidation of pyruvic acid which is formed from lactate When there is insufficient aneurin carbohydrate metabolism is held up at this point and an excess of pyruvic acid accumulates in the blood (Peters 1939) It follows that any condition in which carbohydrate metabolism is excessive predisposes to beri beri in that aneurin requirements are heavier When in addition the vitamin B intake is reduced at the same time as in chronic alcoholism vomiting of pregnancy and thyrotoxic crises beri beri may well develop

The normal requirement of aneurin is about 1 mg daily for an adult and is supplied adequately by the ordinary European diet Special ulcer diets however unless supplemented may be deficient and psychoneurotic—

patients with severe anorexia and vomiting may not receive a sufficient supply of the vitamin Beri beri was common in German concentration camps and Japanese prison camps during the second world war, although usually complicated by other vitamin deficiencies, and has always been relatively common in the Far East when the basic food has been polished rice

Aneurin deficiency is rarely gross in civilised communities and so the presence of some additional factor is commonly needed before the effects of slight deficiencies are brought to light Under these conditions beri beri is atypical for such patients are apt to be middle aged or elderly and the classical signs may be masked by hypertension coronary sclerosis or emphysema in these mixed cases no clear picture of beri beri develops (Konstam and Sinclair 1940)

Behaviour of the heart and circulation The pure disease was studied in Java by Wenckebach (1928 1934) The essential features included a hyper kinetic circulation vasodilatation enlargement of the heart and dilatation of the pulmonary artery Few accurate cardiac output studies have been carried out but the clinical description and the swift circulation time (Weiss and Wilkins 1936–37) leave little doubt that it is high Heart failure may develop suddenly and fulminating cases occur in which death results within 24 to 48 hours of alleged onset of symptoms (Hashimoto 1937) Even in Great Britain cases have been described in which heart failure has occurred remarkably suddenly and unexpectedly leading to a rapidly fatal issue (Wood 1939)

The cause of the hyperkinetic circulation is vasodilatation The drop in peripheral resistance encourages the heart to empty itself more completely whilst the fall in blood pressure causes reflex tachycardia As in all hyper kinetic circulatory states associated with a lowered peripheral vascular resistance (except chronic anæmia) retention of sodium and water by the kidneys increases the blood volume raises the venous pressure and so further increases the cardiac output The remarkable quietening of the circulation that follows the injection of 1 ml of pitressin and the stormy reaction to 1 mg of subcutaneous adrenaline (Wenckebach 1928) confirm the important role of vasodilatation The sudden rise in pulse rate and cardiac output that follow the subcutaneous injection of 10 mg of mecholin or the inhalation of amyl nitrite demonstrate clearly the effect of vaso dilatation on the circulatory hæmodynamics in normal subjects

The heart itself shows little specific at necropsy, the disturbance being biochemical not structural

Diagnosis The clinical diagnosis of cardiovascular beri beri rests on an appropriate dietetic history the demonstration of a hyperkinetic circula tion radiological appearances showing conspicuous dilatation of the pul monary artery associated with overaction and general enlargement of the heart the response to pitressin and adrenaline associated polyneuritis and on the finding of a raised blood pyruvic acid or reduced amounts of

aneurin in blood (Jansen 1938 Sinclair 1938) or urine (Harris *et al* 1938 McAlpine and Hills 1941)

Peripheral neuritis usually begins with pain in the calves on walking similar in character to intermittent claudication Associated weakness of the legs marked tenderness of the calves numbness and tingling of the fingers and toes loss of deep tendon jerks and glove and stocking anæsthesia are usually found

Evidence of deficiencies in other vitamins especially of the vitamin B group is helpful in proving inadequacy of the diet

Treatment It must be stressed that the symptoms of beri beri may begin abruptly and that the course of the disease may be fulminating death occurring within a few days of the onset Once the diagnosis has been made there may be no time to lose Again the possibility of vitamin B_1 deficiency should always be borne in mind in any case of heart failure of obscure origin Here is one of the fatal forms of heart disease which is curable

The patient should be put to bed immediately and aneurine hydrochloride should be given at once intravenously in an initial dose of 50 to 100 mg The effect is dramatic if not given too late Subsequent doses should be of the order of 10 to 20 mg per day for a fortnight orally or parenterally and followed by an adequate diet An abundance of the other components of the vitamin B group is also advised

Fulminating cases should benefit by repeated injections of pitressin (1 ml 4 hourly) until the vitamin has had time to work but care must be taken to avoid hydræmia by keeping the salt and water intake as low as possible

Chronic alcoholics cases of severe thyrotoxicosis Simmond s disease or anorexic nervosa and women vomiting in pregnancy should be given 2 to 5 mg of aneurin daily as a precautionary measure

PAGET S DISEASE OF BONE

The hyperkinetic circulation associated with extensive active Paget s disease was first clearly demonstrated by Edholm Howarth and McMichael in 1945 The general cardiovascular findings closely simulate those associated with arterio venous aneurysm In the case described by Edholm *et al* the blood flow through actively diseased bones was estimated to be 3 to 4 litres per minute and the total cardiac output was 13 litres per minute The venous pressure was elevated and there was dependent œdema Further observations on other cases of active Paget s disease have shown that the heart is not usually overloaded for it is capable of increasing its output by means of tachycardia or a greater rise of venous filling pressure on the other hand paroxysmal cardiac dyspnœa may then occur (McMichael 1947)

Paget s disease also encourages metastatic calcification especially Monckeberg s sclerosis and calcification of the valve rings of the heart

Extension to the interventricular septum may involve the bundle of His or its branches with the production of complete heart block or bundle branch block respectively (*Harrison and Lennox, 1948*)

Cor pulmonale secondary to thoracic deformity from Paget s disease has also been described (Wilks 1869)

Diagnosis If aortic incompetence and valve calcification are both present the clinical diagnosis of Paget s disease may be overlooked in favour of atherosclerotic aortic valve disease As long as the condition is borne in mind however diagnosis is easy for skiagrams of the bones show charac teristic changes and the blood alkaline phosphatase is very high

HEPATIC FAILURE

It has become increasingly evident that advanced disease of the liver may lead to a hyperkinetic circulatory state in addition to the well known palmar flush and cutaneous spider nævi The usual cause is secondary carcinoma but common cirrhosis and even serious infective hepatitis may be responsible It appears that the liver normally detoxicates some vaso depressor substance and that this substance accumulates when the organ is failing (Shorr *et al* 1945) vasodilatation results in the same chain of physiological adjustments that have been described in arteriovenous fistula and beri beri The remarkable effect of hepatic failure on the circulation may be seen sometimes in advanced cases of heart failure when vaso dilatation replaces peripheral vasoconstriction

CHAPTER XXII

TRAUMATIC LESIONS OF THE HEART AND GREAT VESSELS

SPONTANEOUS LESIONS

SPONTANEOUS traumatic lesions of the heart or great vessels include dissecting aneurysm of the aorta rupture of a hypoplasic aorta or syphilitic aortic aneurysm ruptured valve cusps in bacterial endocarditis rupture of a congenital syphilitic or mycotic aneurysm of a sinus of Valsalva into the right side of the heart rupture of chordæ tendineæ in rheumatic or bacterial endocarditis, and rupture or perforation of the heart or ventricular septum secondary to cardiac infarction or ventricular aneurysm The majority of such lesions have been described elsewhere *as complications of the diseases mentioned* Only *dissecting* aneurysm and rupture of an aneurysm of a sinus of Valsalva into the right side of the heart remain to be considered here

DISSECTING ANEURYSM

Definition

Dissecting aneurysm was so called by Lænnec (1826) and means dissection of the media of the aorta by extravasated blood that has penetrated between its coats from the vasa vasorum or from the lumen of the vessel

Incidence

About 1 per cent of all sudden deaths are due to dissecting aneurysm (Mote and Carr 1942) Hospital records which include relatively few such deaths give an approximate incidence of one dissecting aneurysm in every 450 necropsies The Registrar General s figures for 1953 show it to be responsible for about 0 5 per cent of all cardiac deaths in England and Wales Men are more susceptible than women in the ratio of 2 5 1 (Levinson *et al* 1950) Patients are commonly between 50 and 60 years old but 24 per cent are under 40 (Schnikter and Bayer 1944) and cases have been recorded in children (e g Galbraith Gardner and Hardwick 1939) About 50 per cent of dissecting aneurysms in women have occurred during pregnancy (Schnikter and Bayer 1944)

Etiology and pathology

Virchow s original conception that dissection follows an intimal tear at the site of an atheromatous ulcer is no longer tenable for a tear at such a site is now known to be rare (Shennan 1934) Although hypertension and atheroma are usually associated they are not essential the intima may be normal and not even ruptured (Tyson 1931)

Dissection is always within the media commonly begins in the ascending aorta and appears to be closely related to cystic medial necrosis (Erdheim 1929) The cause of such necrosis is unknown Tyson s thesis that it was due to obliterative endarteritis of the vasa vasorum has not been con firmed Cystic necrosis without dissection may be found sometimes in routine necropsies (Moritz, 1932 Rottino 1939) Whether hæmorrhage into the diseased media commonly follows an intimal tear, or whether it comes from the vasa vasorum (the intimal tear then being due to secon dary rupture) remains uncertain When the intima is intact hæmorrhage obviously cannot come from the lumen of the aorta On the other hand intimal tears may undoubtedly be primary for they may occur in healthy ascending aortas without subsequent dissection (Peery 1942) Occasionally hæmorrhage occurs into an area of cystic necrosis of the media without dissection the hæmatoma then becoming organised and causing no trouble (Shennan 1934)

It has recently been suggested that cystic medial necrosis and dissecting aneurysm may be due to defective formation or excessive destruction of chondroitin sulphate the chief mucopolysaccharide of the ground sub stance of the aorta (Ponseti and Baird 1952) These authors noted the high frequency of dissecting aneurysm and kyphoscoliosis in growing rats fed on 50 per cent sweet pea meal the toxic agent being β aminoproprionitrile The fault in the ground substance that results from this agent is believed to be responsible for both skeletal and aortic flaws Bean and Ponseti (1955) found that seven out of 27 clinical cases of dissecting aneurysm had gross kyphoscoliosis

Dissection not infrequently complicates congenital hypoplasia of the aorta usually part of Marfan s syndrome an inherited mesodermal dyscrasia which may well incorporate faulty ground substance A similar flaw may explain the frequency of aortic rupture or dissection in cases of coarctation of the aorta

Dissection may spread proximally and involve the root of the aorta causing aortic incompetence occasionally the coronary arteries are dis sected and occluded Dissection usually spreads distally however may travel the whole length of the aorta and may proceed along any of its branches Ischæmic effects from occluded visceral or parietal vessels are common The majority of cases die from external rupture usually into the pericardium (Strassmann 1947) sometimes into the left pleural cavity or elsewhere Occasionally dissection associated with an intimal tear in the ascending aorta ruptures back into the lumen of the vessel at some distal point forming an alternative or double aortic channel (double barrelled aorta) This is found in the majority of cases that recover (Shennan 1934)

Clinical features

Dissection of the aorta may be precipitated by effort (Gager 1928) but is more often spontaneous A typical attack begins suddenly with severe

pain in the centre of the chest or in the præcordial area The pain may be gripping tearing shooting, or vice like and usually lasts for hours it may radiate to the head and neck to the back—less often to the arms Later in the attack it may spread to the lumbar regions or abdomen and occasionally to the legs depending on the extent of the dissection In perhaps half the cases however pain is slight or absent (Baer and Goldburgh 1948)

Breathlessness is nearly as common as pain (Hamburger and Ferris 1938) and syncope occurs in about 10 per cent of cases (Levinson *et al* 1950) Attacks may therefore closely resemble coronary thrombosis but in cases that survive the blood pressure usually remains high and the electrocardiogram normal moreover, dilatation of the aorta may often be seen in skiagrams (fig 22 01) (Wood, Pendergrass and Ostrum 1932) Fever and leucocytosis are the rule not the exception (Baer and Goldburgh 1948)

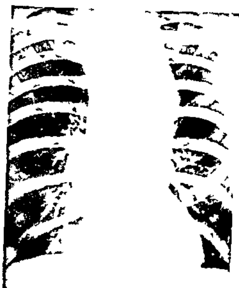

Fig 22 01 —Dissecting aneurysm of the aorta

Other findings depend upon the site and extent of the dissection upon which branches of the aorta are occluded and upon the site of external rupture Aortic incompetence may develop when the root of the aorta is dissected (Weiss 1935) and is being noted with increasing frequency (David *et al* 1947) myocardial infarction may occur if the left or right coronary artery is occluded giving rise to the appropriate electrocardiographic pattern (Wainwright 1944) Pericardial friction is heard occasionally and hæmopericardium may be recognised before death

Dissection of major arteries leads either to occlusion of the vessel or to increased amplitude of pulsation due to spontaneous periarterial sympathectomy (Weisman and Adams 1944) Occlusion of one or other of both carotid arteries may cause hemiplegia mental confusion or coma of the anterior spinal artery, paraplegia of arteries to the limbs loss of the peripheral pulse and perhaps ischæmic pain of the renal artery, hæmaturia —and so on Occasionally a pulse that has been absent may re appear a a result of rupture re entry (Lawrence 1935) A systolic murmur and thrill may develop over partly occluded vessels including the aorta (McGeachy and Paullin 1937) Left hæmothorax is found in about 12 per cent of cases (Baer and Goldburgh 1948) Hæmorrhage into the mediastinum may be responsible for cough and dysphagia An abdominal mass may become

palpable Hæmoptysis hæmatemesis and hæmaturia occur occasionally

Cases that survive the original dissection may present themselves later with congestive heart failure associated with aortic incompetence When there has been no history of pain such cases have usually been diagnosed erroneously as syphilitic aortic incompetence despite negative Wassermann reactions (Gouley and Anderson 1940 Flaxman 1942)

Angiocardiography may help to prove the diagnosis (Golden and Weens 1949) but is not advised in the acute or subacute stage

Prognosis

According to Shennan (1934) about 10 per cent of all cases of dissecting aneurysm recover from the attack usually owing to rupture re entry The majority succumb later to heart failure either as a result of aortic incompetence or from associated hypertensive heart disease

Treatment

No treatment is likely to influence the course of dissection Morphine should be given freely to combat pain If the patient survives the initial attack he should be kept in bed for at least a month

RUPTURE OF AN ANEURYSM OF AN AORTIC SINUS (SINUS OF VALSALVA) INTO THE RIGHT ATRIUM RIGHT VENTRICLE OR PULMONARY ARTERY

Aneurysm of one of the aortic sinuses may be congenital syphilitic or mycotic Rupture of such an aneurysm into the pericardium or left pleural cavity is immediately fatal but perforation into the right atrium ventricle or pulmonary artery leads to a well defined clinical syndrome which may be compatible with many years of active life

Incidence

The condition is rare indeed the author has only encountered and investigated four living instances Congenital cases may occur in young adults syphilitic cases in later life and mycotic at any age About 80 per cent of reported cases have been in men aged 20 to 67 (Oram and East 1955)

Physiology

Rupture into the right atrium causes a large arteriovenous shunt into that chamber overloading of the right heart and the rapid development of congestive failure Cardiac catheterisation reveals a left to right shunt at atrial level Perforation into the right ventricle may similarly overload the right heart blood samples and intracardiac pressures are similar to those in ventricular septal defect (R A P 0 R V P 12 P A P 15 mm Hg S V C and R A samples 44 to 45 R V and P A samples 28 ml oxygen unsat per litre in a case seen by the author)

(a) Anterior view showing engorged pulmonary circulation enlargement of the left ventricle and resection of the 5th rib on the left side (the case having been operated on for patent ductus)

(b) Second oblique view showing enlargement of the left ventricle and dilatation of the pulmonary artery

Fig 20 02—Case of ruptured mycotic aneurysm of aortic sinus into the pulmonary artery

Perforation into the pulmonary artery sets up similar features to patent ductus arteriosus (fig 20 02) In one such case investigated by the author due to a perforated mycotic aneurysm from bacterial endocarditis (cured by penicillin) samples from the right atrium and ventricle showed 67 to 70 ml oxygen unsaturation per litre whereas pulmonary artery samples were only 33 to 36 ml unsaturated The mean right ventricular pressure was 31 mm of Hg above the sternal angle and the pulmonary artery pressure 63 mm Hg

Clinical features

Pain may occur from involvement of the orifice of one or other coronary arteries but is otherwise absent The onset is usually signalled by the rapid development of congestive heart failure but not necessarily The two cases mentioned above were by no means incapacitated and one is still alive 15 years after the onset

The chief signs are a loud machinery murmur accompanied by a thrill over the base of the heart but at a lower level than that associated with patent ductus arteriosus accompanied by signs of aortic incompetence and by features resembling those of ventricular septal defect or patent ductus according to the site of the perforation

Prognosis

Rapid deterioration to a fatal outcome is said to be the rule (Abbott 1919) but this may be because the diagnosis is usually only made at autopsy Three of the author s four cases are not only alive but relatively well the fourth died of heart failure

EFFECTS OF DIRECT INJURY

Direct injury to the heart may be caused by stab or gunshot wounds and very rarely by diagnostic procedures such as needling the pericardium The literature on the subject has been well surveyed by King (1941) and by Barber (1944)

GUNSHOT WOUNDS

A bullet or piece of shrapnel may perforate the heart through and through may lodge in the myocardium or pericardium with or without perforation of one or more chambers or may graze the surface of the heart without causing death In an analysis of 25 instances of war wounds involving the heart made in conjunction with Nicholson in 1945 the relative incidence of such lesions was as follows

Near misses	4
Grazes or tangential wounds	4
Through and through perforation	3
Foreign body in pericardium	7
Foreign body in myocardium	7

Of 1 640 consecutive penetrating chest wounds the heart was directly or indirectly injured in 1 7 per cent The immediate result is hæmopericardium and the rapid development of cardiac tamponade If a foreign body passes close to the heart or lodges within half an inch of its surface a transient pericardial serous effusion may develop If the patient does not die from cardiac tamponade or hæmorrhage into the pleural cavity complete recovery may follow whether or not a metallic foreign body remains in the heart

The chief complication during convalescence is recurrent acute pericarditis this is nearly always associated with the presence of a foreign body either in the pericardium or closely connected with it (Wood 1945) it rarely arises when a bullet is embedded deeply in the myocardium The attacks tend to be severe with pain fever tachycardia gross electrocardiographic changes and the rapid development of a sterile serous effusion which may cause cardiac tamponade They usually last about a week The first attack may occur at any time during convalescence up to about three months after the injury and may recur several times at intervals of about a month Of five such cases studied by the author in the second world war all finally recovered three without interference and two after removal of the foreign body by Nicholson (1945)

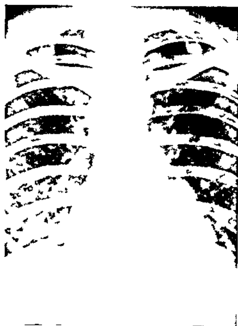

Fig 22 03—Machine gun bullet imbedded in the right atrium

Fig 22 04—Skiagram taken in 1937 showing machine gun bullet embedded in the heart since 1917

A second complication is coronary thrombosis during convalescence when a pericardial foreign body is in contact with a major coronary vessel but this was observed only once

Diagnosis The possibility of cardiac injury should be considered in all cases of gunshot wounds of the trunk or neck especially if the missile is judged to have been directed towards the heart or if its direction is not known for certain Early diagnosis depends upon recognising the signs of cardiac tamponade or hæmopericardium (page 661) An electrocardiogram may be most helpful by showing the presence or absence of the pericardial T pattern

Intracardiac or pericardial foreign body may be readily detected by means of fluoroscopy its movement with the heart beat aiding recognition but it may be easily overlooked in skiagrams

Treatment It is impossible to say how many lives might be saved by early surgical repair of cardiac wounds In the second world war the majority of cases that survived long enough to be evacuated to general hospitals recovered

Relief of cardiac tamponade by paracentesis may be life saving both in the early stages or during a later attack of acute pericarditis Metallic foreign bodies lodged in the pericardium are best removed in view of the danger of recurrent pericarditis Although none of the attacks witnessed proved

fatal the episodes were most alarming Intracardiac foreign bodies should probably be removed if superficial and left alone if deep

Prognosis Only one of the twenty five patients mentioned previously died but as already stated these were favourable cases in that they had survived until evacuated to a general hospital

Follow up studies are incomplete but the worst case with three attacks of recurrent pericarditis and a machine gun bullet embedded in the wall of the right atrium was alive and well two years after being wounded (fig 22 03)

In 1937 the author had the opportunity of investigating a healthy man with a machine gun bullet embedded in his heart since 1917 An unsuccessful attempt to remove the bullet was made at the time An electro cardiogram taken by Sir James Mackenzie showed the usual pericardial T pattern Twenty years later effort tolerance was excellent there were no abnormal physical signs and the electrocardiogram was normal X rays showed the bullet still embedded in the heart in close relationship to the apex of the interventricular septum (fig 22 04) This case was reported in detail by Grey Turner (1941) On the whole it seems likely that the ultimate fate of these patients is favourable

STAB WOUNDS OF THE HEART

Direct injury to the heart in civil life is usually due to single or multiple stab wounds the majority of which penetrate the right ventricle The clinical physiological radiological and electrocardiographic features of cases that have survived long enough to receive medical aid have been chiefly those of hæmopericardium (Wood 1937) Death from hæmorrhage into the pleural cavity or from cardiac tamponade may be prevented by timely surgical repair

Even when patients appear to be holding their own it is probably wise to evacuate the blood clot and to repair and sterilise the wound as soon as possible for hæmorrhage may continue or recur and serious cardiac tamponade develops in most cases Moreover if tamponade is unrelieved too long acute coronary insufficiency may seriously impair the function of the myocardium and when it is finally relieved death may result from acute heart failure The development of a bulge on the left border of the heart simulating the appearances of ventricular aneurysm should not deter the surgeon for this is likely to prove no more than a localised pericardial hæmatoma (fig 22 05)

Fig 22 05—Localised pericardial hæmatoma superficially resembling a cardiac aneurysm

EFFECTS OF INDIRECT INJURY

Indirect injury to the heart may be caused by crushes blows falls or blast The effects include sudden death from ventricular fibrillation or standstill rupture of the aorta rupture of one or more chambers of the heart rupture of the aortic or mitral valve, hæmopericardium myocardial bruising auricular fibrillation and heart block Coronary occlusion and subsequent angina pectoris or cardiac infarction may also occur but their relationship to trauma is less well understood

SUDDEN DEATH

A heavy blow to the region covering the heart may cause sudden death from ventricular fibrillation or cardiac rupture both naturally and experimentally in dogs (Bright and Beck 1935)

There have been numerous instances of sudden death resulting from relatively minor trauma of a kind quite incapable of damaging the heart The catastrophe is then ascribed to ventricular fibrillation or cardiac standstill induced by neurogenic shock Sudden immersion in icy water extreme fright or a blow over the heart insufficient to cause material damage may each act in this way This type of death is similar to that which may be caused by a small pulmonary embolism in experiments in dogs the size of the embolism being quite insufficient to embarrass the circulation and death being preventable by atropine The mechanism is probably a vagal reflex

Rupture of the aorta is more likely to occur from a fall, especially if there is congenital hypoplasia as in many cases of coarctation Hæmorrhage is usually into the pleural cavity or pericardium

RUPTURE OF THE HEART

Rupture of one or more chambers of the heart following trauma is not always immediate nor does it always cause sudden death A myocardial bruise may result in cardiac aneurysm or delayed rupture usually during the second week as described by Bright and Beck These authors collected over 150 cases of traumatic rupture of the heart from the literature and found the incidence of the various chambers involved to be as follows

Left ventricle	37
Right ventricle	31
Left auricle	30
Right auricle	36
More than one chamber	13
Interventricular septum	11
Interauricular septum	1

It will be appreciated that this distribution is very different from that seen with spontaneous rupture secondary to cardiac infarction when the left ventricle is nearly always responsible

The [illegible]tent interval was studied by Warburg (1938) It occurred in 15 out of 51 cases proved at necropsy A small tear may behave similarly to a direct penetrating wound that causes delayed death from hæmopericardium usually within a few days A bruise may rupture at any time within six weeks (Barber 1938) or occasionally after a longer interval Cardiac aneurysm resulting from a bruise may rupture years afterwards (Joachim and Mays 1927)

During the quiescent phase the patient may seem relatively well any discomfort being attributed to the bruise on the chest and he may continue his normal activities including sport (Priest 1939) In other cases symptoms may result from hæmopericardium or from any of the other effects to be described presently

Diagnosis

If the patient is seen alive after cardiac rupture the signs and symptoms are those of hæmorrhage into the pericardium or pleural cavity The combination of collapse rapid thready pulse and a high jugular venous pressure from cardiac tamponade is very suggestive if discovered within a month of injury There may be no evidence of external damage to the chest wall and the history of the accident may not be mentioned for it may not appear to be connected with the illness If the possibility of previous trauma is considered the diagnosis is usually obvious

Treatment

Immediate surgical repair is the only hope of saving life

HÆMOPERICARDIUM

Symptoms and signs of pericarditis with or without hæmopericardium are relatively common after indirect cardiac trauma particularly perhaps after blast injury They provide useful evidence of cardiac damage but do not necessarily indicate its nature Surgical interference is only warranted if there is tamponade which usually signifies cardiac rupture or serious coronary hæmorrhage Many cases have recovered spontaneously (Smith and McKeown 1939)

MYOCARDIAL BRUISING

Crushing of the chest direct blows over the heart and blast may all cause myocardial contusion the clinical picture resembling that of myocardial infarction including the characteristic electrocardiographic changes or heart failure without pain (Barber 1940 Barber and Osborn 1941)

Following a direct blow in the præcordial region, electrocardiographic changes may occur which are indistinguishable from those of posterior myocardial infarction (Anderson 1940) In these cases it may be assumed that the right coronary artery has been injured anteriorly

The chief danger of myocardial contusion is delayed rupture as previously described

Treatment consists of rest in bed for six weeks semi starvation a low sodium intake mersalyl if necessary sedatives, and avoidance of digitalis

RUPTURED AORTIC CUSP

Indirect trauma sometimes ruptures an aortic cusp There may or may not be underlying aortic valve disease congenital or acquired The lesion results in the abrupt development of aortic incompetence which throws a heavy burden upon an unprepared left ventricle so that failure of that chamber is likely to ensue

The diagnosis is suggested by the sudden onset of orthopnœa paroxysmal cardiac dyspnœa or pulmonary œdema following a serious fall or other violent accident and is confirmed by the discovery of a loud, harsh sometimes musical aortic diastolic murmur often accompanied by a thrill especially if the valve was known to have been normal previously

The prognosis may be good if the patient survives the immediate insult but death from heart failure within six weeks is a grave risk (Barber 1938 1944) Treatment consists of six weeks rest in bed in order to allow time for adequate compensation and may have to be directed towards combating left ventricular failure It must be understood that a degree of aortic incompetence which would be well tolerated and consistent with years of active life if it had developed slowly may cause death from acute heart failure when it occurs abruptly just as acute hypertension may cause left ventricular failure and pulmonary œdema whereas much higher pressures may be tolerated when developing slowly in benign hypertension

TRAUMATIC MITRAL INCOMPETENCE

A severe fall or sudden blow over the heart or other violent accident may occasionally rupture chordæ tendineæ or tear one of the mitral cusp particularly if already diseased The lesion is rare but there are many well authenticated instances (Barber and Osborn, 1937) A clinical diagnosis may be made from the history if it is known that no murmur was present before the accident if a loud harsh mitral systolic murmur is heard when the heart is first examined after the accident if there is no evidence of previous rheumatic valve disease and if confirmatory signs of organic mitral incompetence develop (page 506)

A number of cases have died from congestive heart failure within a few hours or weeks of the accident and others have developed mitral stenosis later (Barber, 1938) On the other hand the accidental discovery of symptomless mitral incompetence attributable to trauma need cause little alarm such cases behaving like rheumatic mitral incompetence with a healthy myocardium

HEART BLOCK

There have been a number of instances of asphyxia in which hæmorrhage has taken place around the bundle of His with resulting heart block Several

cases have been seen at necropsy by the author, and a good example was observed during the 1940–1 London air raids

A woman of about 35 known to have been in previous good health was rescued in a partly asphyxiated condition from beneath a lot of debris Examination shortly afterwards revealed not only complete heart block but also gross signs of hemi Parkinsonism presumably due to hæmorrhage into the bundle of His and into the substantia nigra She declared that she had received no severe blow on her chest nor significant crush but had been partly asphyxiated by dust for about one hour

Heart block may also result from a blow over the heart or from a fall on the chest (Coffen, 1930 Warburg 1938), and has been so produced experimentally in dogs (Kissane, 1937) Hæmorrhage into the conducting system is presumably responsible The lesion may be transient or permanent the prognosis depending on the presence or absence of Stokes Adams fits and upon the rate of the idioventricular pace maker, but on the whole it is *fairly good* provided there is no more serious injury and provided the heart muscle is sound

AURICULAR FIBRILLATION (OR FLUTTER)

Several cases of auricular fibrillation caused or precipitated by blows have been reported (Kahn and Kahn 1928) particularly in the elderly (Barber 1938) Bramwell (1934) records a case in which auricular fibrillation was probably initiated by a head injury, and Hay and Jones (1927) describe one due to electric shock

The mechanism whereby head injury may cause auricular fibrillation is particularly interesting though still obscure There is reason to believe that parasympathetic activity may be culpable Thus digitalis which stimulates the vagus, may cause auricular fibrillation and there is a form of sinus bradycardia due to vagal influence which is associated with paroxysms of flutter or fibrillation In experiments on certain animals fibrillation may be induced by vagal stimulation Not only head injury but also meningitis Meniere s syndrome and probably other intracranial disturbances may excite this rhythm change

CARDIAC INFARCTION AND ANGINA PECTORIS

As already described myocardial contusion may give rise to clinical and electrocardiographic features similar to those of myocardial infarction and may also result in cardiac rupture or aneurysm There appears to be a closer relationship however between trauma and ischæmic effects For example an anterior injury to the chest may cause a posterior left ventricular lesion clinically indistinguishable from a cardiac infarct and classical angina pectoris may develop for the first time immediately after trauma (Campbell 1939) Moreover the subsequent course of these cases may be that of ordinary ischæmic heart disease It is possible that blows crush injuries and blast may injure the anterior coronary vessels either by causing sub

intimal hæmorrhage in an atherosclerotic artery or more directly and thus cause acute coronary occlusion or secondary thrombosis After such an event subsequent angina pectoris would be readily understood Great care must be taken in diagnosing traumatic angina however, for many persistent chest pains following injury represent compensation neurosis

Treatment consists of three to six weeks rest in bed followed by one to three months convalescence to allow time for the development of adequate collateral vascularisation The prognosis depends upon the degree of underlying coronary disease as well as upon the amount of damage inflicted On the whole it is not dissimilar to that in ischæmic heart disease in general

MEDICO LEGAL ASPECTS

Employees are entitled to compensation if it can be shown that trauma has initiated or aggravated a cardiovascular disability Even a case of syphilitic aneurysm that ruptures during the course of work receives compensation Patients with established heart disease may deteriorate after an accident and this aggravation is equally compensated The benefit of doubt is always given to the patient and in a court of Law or a tribunal it is difficult to convince a judge or president that trauma has not adversely affected the cardiovascular system Yet a firm stand must be taken over the development of cardiac neurosis Left inframammary pain is especially liable to become persistent and intractable if linked to the idea of compensation and the physician must be prepared to make a categorical statement to the effect that this is not organic and is not due to the accident that it origin lies in the mind and in the emotions and its growth runs parallel with the conscious or subconscious desire for gain

CHAPTER XXIII

CARDIOVASCULAR DISTURBANCES ASSOCIATED WITH PSYCHIATRIC STATES

THE cardiovascular system may be profoundly influenced by psychological or psychiatric states through the medium of the autonomic nervous system The stimulus is emotional and appears to act on the central vegetative nuclei in the region of the hypothalamus We are all familiar with the uncomfortable thudding of our hearts during moments of fear and most of us have witnessed a fainting attack provoked by the sight of something that is at once queer and frightening The physiological basis for such phenomena is relatively simple sympathetic or adrenergic activity may cause palpitations by accelerating the pulse elevating the blood pressure and strengthening the heart beat parasympathetic or cholinergic activity may induce syncope by retarding the pulse lowering the blood pressure and weakening the heart beat

Cardiovascular upsets of this kind sufficient to bring the patient to seek medical advice almost invariably indicate psychiatric disorder for the effects of emotion within the limits of common physiological experience are too transient and too familiar to disturb a normal individual Moreover in psychiatric states such symptoms may be persistent or may be provoked too readily The syndrome so produced has been called soldier s heart irritable heart disordered action of the heart (D A H) cardiac neurosis effort syndrome autonomic imbalance neurocirculatory asthenia etc Such terms should be discarded in favour of the correct psychiatric diagnosis but the words effort intolerance may be added with advantage preferably in brackets when clinically important Historically one may speak of Da Costa s syndrome to cover all previous nomenclature (Wood 1941)

The syndrome is characterised by a group of symptoms which unduly limit the subject s capacity for effort or which upset his peace of mind at rest by a number of signs which depend upon disturbance of the autonomic nervous system and by an underlying psychiatric disorder The cardinal symptoms are breathlessness (93 per cent) palpitations (89 per cent) fatigue (88 per cent) left inframammary pain (78 per cent) and dizziness (78 per cent) or syncope (35 per cent) The cardinal signs are those of functional disturbance of the respiratory vasomotor sudomotor and muscular systems The psychiatric disorder is commonly an anxiety state but may be almost anything with high emotional content including the psychoses

It should be understood that there is no essential difference between effort syndrome and cardiac neurosis they are merely clothed differ

ently the former in battle dress the latter in nylon In civil life the condition accounts for 10 to 15 per cent of all cases referred to cardio vascular clinics it is common in children and occurs more often in women than in men the ratio being 3 2 It has a preference for the emotional races especially the Jews and the Italians In the first world war there were some 60 000 ' effort syndrome casualties n the British forces in the second a more enlightened view was taken, the majority of these cases receiving appropriate psychiatric labels and management

CLINICAL FEATURES

The cardinal symptoms and signs have already been mentioned, they will now be discussed in more detail

Breathlessness These patients experience a true sensation of breathlessness in circumstances that would not affect a normal person It is not only a question of breathlessness on effort but patients will say they are unable to obtain a satisfying breath, or that they feel a sense of suffocation and this is confirmed objectively by frequent deep sighs Sometimes they complain of attacks of noctural dyspnœa which may be confused with bronchial asthma or with paroxysmal cardiac dyspnœa careful questioning however should reveal their psychosomatic nature especially by probing the precipitating anxiety dream and by unmasking the associated panic state Further evidence of functional respiratory disorder may be obtained by noting hurried irregular and shallow breathing A simple and illuminating test is forced hyperventilation The patient is asked to breathe deeply and rapidly for one minute A normal individual experiences dizziness and sometimes slight tingling of the fingers and toes When told to stop he passes into a state of apnœa lasting about 20 seconds The psychoneurotic especially the hysteric dramatises his subjective sensations and when told to desist usually continues forced breathing explaining later that he felt breathless Since dizziness is due to cerebral vasoconstriction induced by carbon dioxide washout it is clear that such psychoneurotics experience breathlessness when the carbon dioxide content of the arterial blood is so low as to cause apnœa in controls The respiratory stimulus must therefore come from higher centres The maximum breath holding time is another useful test Normal subjects have no difficulty in holding the breath for at least 30 seconds but patients with Da Costa s syndrome usually give up very quickly 30 per cent of them in less than 10 seconds moreover in contrast to controls they show little distress when they reach the breaking point

Palpitations Cardiac overaction resulting from emotional stimulation plays an important role in the induction of cardiac neurosis It is a common psychiatric event for some intangible fear to become linked to something more easily understood and remote from the real difficulty For example a psychoneurotic with a morbid fear of heights may develop palpitations

when ordered to climb a ladder If the idea that palpitations may denote some disorder of the heart occurs to him he at once embraces the possibility and proceeds to advance the theory in all seriousness for it disguises his true fear which might be thought shameful and protects him from the danger Although a successful defence mechanism in these two respects the manœuvre is baneful because it provokes a new fear that of heart disease and sudden death this new fear aggravates the palpitations and so closes a vicious circle

The palpitations of anxiety states are associated with sinus tachycardia elevation of the blood pressure increase in cardiac output and probably with strengthening of the heart beat These features are due essentially to emotional stimulation of a normal adrenergic system

Fatigue Patients often complain that they do not feel refreshed when they wake in the morning that their sleep has been of no benefit to them They also feel tired and listless during the day, and are unduly fatigued by effort The symptom is usually attributed to anxiety dreams and to emotional conflicts

Left inframammary pain Psychosomatic pain is usually situated in the left inframammary region but may be higher lower more central or more lateral it may radiate down the left arm It is commonly described as aching or as sharp and stabbing in quality but occasionally it is constricting or cramp like Although pain may occur during effort it is more frequent afterwards it is also common at night and may prevent the patient sleeping on the left side sometimes it is capricious and bears no relationship to any known factor Sharp twinges are momentary and acute stitch like pain may last several minutes but the classical ache usually continues for hours It thus usually differs from angina pectoris in its eccentric site its quality relationship to effort and duration i e in every important respect Occasionally however as may be inferred from the description given above psychosomatic pain may be situated near the left border of the sternum referred to the left arm constricting in quality and measured in minutes In such cases it may well be misinterpreted There is usually some odd remark however or something in the patient s manner which should warn the physician and encourage him to launch a critical cross examination The precise history of angina pectoris will not be shaken by this but that of an anxiety state alters and becomes more complicated and confused when elaborated

Left inframammary pain is important because it seems to convince the patient that his heart is diseased and it is not unnatural that he should think thus of a pain arising so close to it In the psychoneurotic this creates a morbid fear of death and catastrophe and so closes another vicious circle

The exact mechanism of the pain is obscure It is immediately abolished by the intramuscular injection of 2 ml of novocaine at the site of maximum intensity or tenderness Cutaneous or subcutaneous anæsthesia has no

effect This indicates that it is not referred but arises locally in muscle or fascia and suggests that it is related to 'fibrositis' and low back pain It may be initiated by fatigue or strain of respiratory muscles in cases with respiratory neurosis by strain of certain muscular attachments involved in such actions as cranking an engine or lifting a heavy weight, by incessant minimum trauma from the light hammer blows of an overacting heart or by faulty posture It is exaggerated and perpetuated by the belief that it arises in the heart

Dizziness Dizziness means momentary faintness, transient unsteadiness light headedness , or a far away feeling It does not refer to spinning as in vertigo It may occur on sudden movement of the head on standing up abruptly or during effort It is readily reproduced by hyperventilation when it is attributed to cerebral vasoconstriction Orthostatic dizziness is related to orthostatic hypotension, and is due to inadequate circulatory adjustments on assuming the erect posture It is probable that other forms of dizziness are also due to diminished cerebral blood flow induced by autonomic disturbance Transient loss of consciousness due to temporary failure of the cerebral circulation occurs at one time or another in 20 to 30 per cent of these cases

Sweating Sweating is a helpful diagnostic feature because in the majority of instances it is confined to the axillæ the palms of the hands and the soles of the feet These are emotional sweat areas Thermal sweating and that induced by cholinergic drugs, have a different distribution being much more widespread Sweating associated with effort may begin emotionally but is soon thermal Thyrotoxic sweating is also thermal The hands are the best single guide if sweating is confined to the palms the stimulus is emotional if the backs of the hands are also involved other causes should be considered Undue sweating is mentioned or admitted by 80 per cent of these cases and is seen objectively in about two thirds

Headache Headache is a common complaint (72 per cent) and is either vague or throbbing In assessing the reality of the physical basis of the throbbing type it is helpful to ask the patient to count the throb aloud or better to tap out the rhythm digitally while the observer checks this against the pulse rate in true vascular headache they must coincide in hysteria they do not Unilateral carotid compression is also useful for it abolishes vascular headache on the same side but it either aggravates or has no effect upon hysterical pain Throbbing vascular headache may be induced by the intravenous injection of 1 mg of histamine or by trinitrin or amyl nitrite in some cases It is closely associated with exaggerated pulsation of the cerebral arteries (Pickering 1939) It is seen clinically not only in the anxiety states but also in fevers and in acute alcoholism It occurs spontaneously in migraine Improvement depends upon better autonomic regulation, which in turn depends upon successful treatment of the underlying anxiety state

Fig 23 01—Clas ical facies build and posture of a case of Da Costa s syndrome Painted by Ian Tillard (l fe size portrait in the museum of the Post Graduate Medical School of London)

PHYSICAL SIGNS

Signs of autonomic disturbance serve to check the validity of psycho somatic symptoms Most have already been mentioned but they will be recapitulated and grouped here for convenience

General
- Tense dejected or diffident manner
- Dull weak or listless facies
- Soft quiet timid voice

Cardiovascular
- Tachycardia (30 per cent)
- Overaction of the heart (44 per cent)
- Blood pressure in the region of 150/90 mm Hg (27 per cent above)
- Deceleration time over 2 minutes in effort tolerance test (33 per cent)
- Acrocyanosis (44 per cent)
- Flushes (36 per cent)

Respiratory
- Frequent deep sighs (32 per cent)
- Rapid irregular or shallow breathing occasionally hyperventilation (21 per cent)
- Inability to hold the breath for 30 seconds (76 per cent)
- Dyspnœa instead of apnœa after forced breathing

Sudomotor
- Visible sweat on the palms of the hands (67 p r cent)
- Sweat trickling from the axillæ (35 per cent)

Skeletal and Muscular
- Tremor of fingers usually coarse irregular and inconstant (6 per cent)
- Shakiness of voice and limbs
- Asthenic posture or poor physical development (41 per cent)
- Tenderness in area of left inframammary pain

A life sized portrait of one of these patients (fig 23 01) hangs in the library of the Postgraduate Medical School of London and surpasses any description The effort tolerance test consists of stepping on and off a chair ten times and counting the pulse rate before immediately after and subsequently at minute intervals until the resting speed is regained The deceleration time is abnormal (over 2 minutes) in 33 per cent of these patients

Physical signs of autonomic disturbance are helpful in distinguishing the malingerer and in assessing the severity of the case About 90 per cent of normal young adults do not show more than one of these signs and 50 per cent show none

PSYCHIATRIC ASPECTS

Although the syndrome described may occur in any psychiatric state with high emotional tone it is usually associated with an anxiety state In many there are hysterical features and a large number show reactive depression

The family history is tainted with psychoneurosis in 50 to 60 per cent compared with 5 to 10 per cent in controls with or without organic heart disease About 66 per cent describe neurotic traits in childhood morbid fears especially of the dark of heights of water or of animals are frequent bed wetting stammering tics nightmares sleep walking and undue delicacy of health are common They are timid children far too dependent upon maternal protection At school kindly doctors and soft mothers protect them from the hazards of football swimming and the gymnasium

It is probable that predisposition to psychoneurosis is mainly hereditary but early environmental factors such as domestic strife insecurity suppression and maternal coddling play their part

There are many factors which may operate to bring about the adult syndrome and in any particular case one should never be satisfied with the discovery of only one or two It is fruitful to search for evidence of predisposition for a state of mind recently prepared for the development of psychoneurosis by external or by endogenous factors for precipitating agents for the growth of vicious circles and for motives for gain that aggravate and perpetuate the syndrome Proper assessment management and prognosis are impossible if any vital link is overlooked

Hereditary and environmental predisposition have already been discussed *The mind is especially prepared for the development of psychoneurosis* when in a state of confusion and unreality Head injuries may bring this about certain acute fevers are often responsible especially rheumatic fever influenza meningitis and diphtheria long hours of work in unpleasant and unhappy surroundings may be to blame

Precipitating factors are often multiple It is as if one or two could be coped with but when several occur one on top of the other mental equilibrium disintegrates They are usually closely linked with fear in some form or another The most obvious example is active service hence the high incidence of the disorder in war Fear of football and fear of swimming are common in childhood and may precipitate anxiety at school The fear of being unsuccessful of not being able to shoulder responsibility is a common cause of breakdown in civil life Insecurity or fear of the future is also common The adoption of a line of action contrary to established social custom may cause an anxiety state due to fear of discovery and public criticism Difficult personal relationships especially between husband and wife are often responsible Sex difficulties are important, but should not be over emphasised Financial worry unemployment fear of disease play their part To a timid sensitive character the

being found out of being thought a coward, of being proved inadequate of seeming a fool—and so of losing cast, is a very real and powerful emotional stimulus

The *development of vicious circular patterns is interesting* In this particular syndrome most vicious circles have a common basis and revolve round the fear of heart disease and sudden death The combination of breathlessness dizziness or syncope fatigue and especially palpitations and left inframammary pain provides convincing evidence of heart disease to the lay mind All these symptoms which are psychosomatic in mechanism may be produced by simple anxiety and may disappear rapidly as soon as the anxiety is resolved But if the patient takes the fatal step and believes that they are due to heart disease a vicious circle is at once established for a new and greater fear develops that of sudden death at any moment This constant anxiety operating consciously or subconsciously every second of the day and night increases the severity of the psychosomatic symptoms Under these circumstances the syndrome is maintained long after resolution of the original anxiety Superimposed upon this pattern or independent of it there develop various and often complicated conditioned reflexes until finally distressing autonomic reactions are so ingrained and so divorced from conscious thought as to be practically ineradicable Correct medical interpretation of early psychosomatic symptoms is of the utmost importance in the prevention of these pernicious grooves The doctor who misinterprets a boy s fear of water and accepts the pallor and palpitations as signs of heart disease who mistakes left inframammary pain for angina pectoris who finding an innocent systolic murmur diagnoses valvular heart disease who regards syncope or dizziness as a sign of cardiac weakness is guilty not only of stupidity and ignorance but is also responsible for turning his patient into a chronic and incurable psychoneurotic Even so it may be comforting to know that medical blunders of this kind will influence only 10 per cent of apparently normal individuals the great majority adversely affected showing evidence of predisposition

Finally *there* is the motive for gain This is seen in compensation neurosis and in war it is obvious at every medical board The inadequate personality of so many of these patients capitalises the symptoms What timid man indifferent to higher ideals will face the dangers of battle when the very symptoms of his fear offer him protection?

DIFFERENTIAL DIAGNOSIS

The characteristic symptoms and signs associated with psychiatric disorder usually make the diagnosis easy The physical features have been stressed because the psychiatric state may not be obvious until the mind has been deeply probed This is well shown by comparing the conclusions drawn at the special investigation centres for effort syndrome during the

first two world wars at Hampstead in world war I where little attention was paid to psychiatry not more than 10 per cent were considered psychoneurotic at Mill Hill in world war II a psychiatric basis was proved in 94 per cent The diagnosis should be positive not dependent upon a process of exclusion it may stand even when organic disease is also found especially mild rheumatic heart disease benign hypertension and chronic bronchitis

Thyrotoxicosis may present difficulty to the inexperienced The common mistake is to diagnose an anxiety state as thyrotoxicosis rarely the reverse The difference is fully considered on page 874 and 878 Particular attention should be paid to the attitude and behaviour of the patient to the expression of the eyes to the colour and temperature of the hands to the distribution of sweating to the diastolic blood pressure and to the appetite

In children active rheumatic carditis may cause confusion vague muscle pains being mistaken for joint pains and tics for chorea

Attacks of violent palpitations in anxiety states are sometimes confused with paroxysmal tachycardia Accurate history taking and observation of an induced attack should prevent error The special points of difference are given on page 237

The distinction between left inframammary pain and angina pectoris has already been considered but real difficulty may arise In both the diagnosis depends largely upon the history and cannot be proved or disproved by the demonstration of psychoneurosis on the one hand or of organic heart disease on the other The matter is further complicated by the adverse effect of anxiety upon ischæmic heart disease for it may be so important a factor that its satisfactory resolution may temporarily relieve angina pectoris Occasionally the diagnosis remains doubtful until determined by the future course

The physician should be on his guard against pulmonary tuberculosis chronic undulant fever juvenile spondylitis spontaneous hypoglycæmia and certain endocrine disorders—especially the menopause Anæmia should be more obvious When the symptoms first arise during convalescence simple reassurance should be given and the final diagnosis deferred until it is clear that rapid recovery has or has not taken place

TREATMENT

Treatment is never easy and is the more difficult the longer it is delayed Failure is certain if any essential factor in the development of the syndrome is overlooked so that a great deal of time must be spent on these patients Simple reassurance and some superficial explanation are quite inadequate

First the patient must feel that at last he has met a doctor who thoroughly understands his case secondly a complete physical examination supp by fluoroscopy and an electrocardiogram is necessary so that

respect unconditional reassurance Adequate explanation must follow, and will vary according to the chief symptoms The object is to convince the patient that the symptoms are emotionally produced One may point out how sudden fear causes palpitations sweating alteration of breathing and sometimes a fainting attack He will agree with this but may object that he feels no such fear One should then explain that great fear acting for a few seconds may be more than equalled by a tiny remote fear acting over weeks months or years a state called anxiety This step is difficult but the point must be carried Correct interpretation of anxiety dreams is of value in demonstrating the power of subconscious emotion Enlightenment and conviction may come suddenly if psychosomatic disturbance on some particular occasion or under certain specific circumstances can be explained in the light of emotional experience

For example a patient at Mill Hill gave a history of a morbid fear of fireworks in his boyhood conditioned by London air raids in his infancy Otherwise he was fit and strong He was called up in September 1939 was sent to France and remained well until told one day to unload an ammunition lorry On handling the shells he became curiously panic stricken developed gross psychosomatic symptoms and mis interpreted them thinking they meant heart disease A vicious circle was initiated he reported sick and finally arrived at a base hospital with an established effort syndrome When the link between his fear of handling fireworks and his handling shells for the first time was pointed out he was suddenly convinced of the truth of the explanation given for his symptoms and made a rapid and complete recovery But his fear of fireworks shells and all other explosives was unabated Treatment had only been directed towards the removal of effort intolerance by abolishing the misinterpretation and vicious circle that initiated and maintained it

As a rule however it is not enough to reassure and give an adequate explanation for by the time the patient consults a physician the syndrome is usually highly complex and conditioned reflexes are well ingrained To cut across such reflexes and vicious circles, one may encourage the patient to come to better terms with his symptoms He fears them because he thinks they are injurious and may result in sudden death He must be told they are harmless that they can never be more than a nuisance that he is already familiar with the worst they can do Once he appreciates the fact that if he no longer fears his symptoms he will cease to aggravate them the point is scored

If there is an hysterical motive for gain it must be mentioned and then ruthlessly underlined It is remarkable what little insight these patients have, and disconcerting how little shame

The methods so far outlined do not touch the underlying psychoneurosis and the real treatment has yet to begin The patient may be referred to a psychiatrist or if the causative factors seem clear the physician may prefer to deal with them himself There are always three things to consider the difficulties in which the patient is floundering his reaction, which is based

on his character and intelligence and his attitude towards his reaction The difficulties should be taken first sorted out and resolved as far as possible The help of social welfare workers may be enlisted in this respect The patient s reaction should be analysed and some psychiatric skill and knowledge are required to do this It is often possible to show that his reaction is based on false values ideas or beliefs Or one may simply explain just why he so reacts in order to give him insight It is impossible to outline precisely just what is required for every case is different and needs individual treatment If the problem has no satisfactory solution and if the patient s reaction cannot be altered favourably then at least he may learn to get on better terms with both Difficulties must be faced and not hidden away in the dark recesses of the mind highly personal matters should be fully discussed in a matter of fact way until they cease to seem so dreadful if a man is standing on a false pedestal he must learn humility and honesty and tread upon the good earth

Finally the background must be assessed With strong hereditary taints and bad early environment the outlook is poor and the aim should be to fit the patient into circumstances which will cause the least embarrassment This is a confession of failure At the other extreme if the stock is good and if there is no evidence of predisposition and if this is confirmed by the severity of the stress of anxiety causing the breakdown every effort should be made to cure the patient In other words one should deal with the environment when the prognosis is bad and with the patient when it is good

ŒDEMATOUS LARYNGITIS

Synonym —Œdema of the Larynx

Ætiology —Œdema of the larynx is not a disease but a pathological condition due to a variety of causes Non inflammatory œdema may be mentioned here for the sake of completeness, it occurs, though rarely, as part of the general anasarca of renal and cardiac disease Angio neurotic œdema sometimes occurs in the larynx in which event it produces rapid and sometimes fatal dyspnœa (see p 1255) The swelling which occasionally results from administration of potassium iodide in susceptible subjects may be placed in the same category

Inflammatory œdema seldom results in adults from a simple catarrh but it may do so in children, it more often occurs as part of an acute septic infection of the pharynx, trachea and bronchi ' acute fulminating laryngo tracheo bronchitis ' (*q v*) Œdema may follow various forms of trauma the drinking of corrosive poisons inhalation of irritating vapours such as the poison gases of warfare the lodgment of foreign bodies or rough or unduly prolonged bronchoscopy Scalding from attempts to drink from a kettle spout is a common cause among children In other cases it is a sequela of typhoid fever, pneumonia, scarlet fever or small pox and is a local complication of syphilitic tuberculous cancerous or traumatic ulceration

Symptoms —If part of a septic pharyngo laryngitis the general symptoms are severe The chief local symptom is dyspnœa with inspiratory stridor and the associated symptoms of asphyxiation there is hoarseness or aphonia local discomfort and tenderness and sometimes dysphagia The aryteno epiglottidean folds are enormously swollen appearing as pale or purple translucent flask shaped masses, if the epiglottis be œdematous it forms a sausage shaped swelling of the same appearance The mucosa of the vocal cords is too adherent to permit much swelling and œdema of the glottis is therefore a misnomer The subglottic region is lax and may become swollen indeed the œdema may be confined to this region and then appears as a red swelling below each vocal cord In children œdema may be inferred from the steadily increasing dyspnœa without the rapid increase and decrease typical of spasmodic laryngitis

Treatment —Patients should be nursed in a semi sitting position In slight cases the swelling may be reduced by sucking ice and by the application of an ice bag to the neck the latter is inadmissible in young children A spray of adrenaline 1 in 1000 may be used Hypodermic injections of pilocarpine, gr ⅛ are recommended, and for the œdema produced by iodides large doses of bicarbonate of soda When œdema is the result of an acute streptococcal infection full doses of sulphonamides and penicillin should be given without delay Scarification of the œdematous tissues with a curved bistoury which was accepted practice in the past is now not recommended because of the disturbance it causes to patients the danger of blood entering the trachea and the chances of giving rise to secondary infection Tracheotomy should be performed before respiratory embarrassment is too great intubation is not recommended Angio neurotic œdema should be treated by a spray of adrenaline but as this condition is often allergic in origin it is logical to prescribe full doses of one of the anti histamine drugs such as promethazine or phenindamine Intravenous calcium gluconate is excellent treatment Very rarely tracheotomy may be necessary

MEMBRANOUS LARYNGITIS

The formation of false membrane in the larynx is nearly always part of an attack of diphtheria which is discussed elsewhere but the term membranous laryngitis implies formation of membrane of non diphtheritic origin Apart from traumatic cases due to irritating chemicals and scalds inflammation of the larynx accompanied by membrane may be caused by streptococcal infection The affection occurs especially in children between the ages of 2 and 8 years (see Acute Laryngo-Tracheo Bronchitis p 946) The diagnosis from diphtheria is only possible by bacteriological examination and pending the report the case should be treated with antitoxin It may be noted that the pharynx is nearly always involved in diphtheria whereas in membranous laryngitis the disease is often primary in the larynx The prognosis is grave and worse than that of diphtheria since the introduction of antitoxin

ACUTE LARYNGEAL CONDITIONS AFFECTING CHILDREN

In the past it has been customary to describe a group of acute laryngeal conditions occurring in early childhood all of which are associated with dyspnœa A great deal of unnecessary confusion has arisen because there has been (and still is) some uncertainty as to the mechanism of such conditions An unfortunate nomenclature has been evolved which is muddling and unhelpful

An attempt will be made to clarify the situation by confining description to acute laryngitis in children acute laryngo tracheo bronchitis congenital laryngeal stridor and laryngismus stridulus

For years the expression croup has been used so universally that many have wrongly supposed that the term denoted a definite disease The word dates from a period when diagnosis of diseases of the throat was far from exact and the meaning was obstructive dyspnœa The adjective croupy may still be used to describe noisy inspiratory stridor, itself a symptom of diverse laryngeal affections

ACUTE LARYNGITIS IN CHILDREN

In young children the larynx is small whilst the cartilages are soft and yielding The mucosa is rather loosely connected to subjacent tissues so that effusion can take place more readily It seems that the controlling nervous mechanism is somewhat unstable and that glottic spasm is more easily evoked For these reasons laryngitis in children is always a serious condition and alarming symptoms especially dyspnœa and cyanosis may develop with extreme rapidity A child save for a slight cough may seem well during the day and then at night may suddenly develop laryngeal spasm and become seriously ill Acute laryngitis with spasm is a better name than the old established laryngitis stridulosa a term which though accurate enough has served to confuse generations of medical students

Treatment—The time honoured treatment has been an emetic and a purge Emetics are certainly helpful in some cases and tincture ipecacuahnæ min 60 may assist in the removal of obstructing secretions An aperient may be given remembering that there is no specific virtue in calomel It is well to put up a steam kettle and there are occasions when oxygen will be required Antibiotics will not directly relieve laryngeal spasm but may be indicated to control the primary infection Very rarely indeed is tracheotomy required When the acute attack has passed the child should be examined with a view to eliminating unhealthy adenoids or tonsils

ACUTE LARYNGO TRACHEO-BRONCHITIS

Ætiology —This severe disease *usually occurs* in children under 3 years of age and is rarely seen after the age of 6 Weakly children are most often affected and the mortality even now is about 15 per cent The responsible organisms may be streptococci, staphylococci pneumococci or influenza bacilli There is redness and swelling of the arytenoid region and gross subglottic swelling which spreads down into trachea and bronchi An exudate is poured out into the tracheo bronchial tree and quickly becomes thick and tenacious, its expectoration is often beyond the strength of the patient Pneumonia and atelectasis from plug formation form a prominent part of the clinical picture

Symptoms —*In most* cases the disease *develops* comparatively *slowly*, *only* occasionally is an infant rapidly prostrated The following graphic description is quoted from F C Emery As the disease progresses these patients become de hydrated prostrated and finally present a picture of complete collapse The cyanosis disappears leaving an ashen pale skin and anoxic coma, with all the remaining energy being spent on breathing Retraction may be so great that the sternum and thoracic spine seem to meet with each gasping inspiration '

Treatment —Humidification of inspired air is important and a steam kettle can be used with advantage Almost all cases must be at some time nursed in an *oxygen tent a mixture of helium and oxygen has been recommended by Jackson* Sleep is a grave problem as drugs given to ensure sufficient rest *damp down* the cough reflex On the other hand continual coughing may so sap the patient s physical strength that some opiate must be given In theory causative organisms *should be* isolated and tested for sensitivity to the various antibiotics and sulphonamides *but* time should not be wasted whilst waiting for the bacteriologist s report Penicillin is generally u eful but evidence is mounting which suggests that *chloramphenicol is* substantially more effective Every effort must be made to *keep up the fluid* intake

Bronchoscopy often becomes an *urgent* necessity for this may be the only practical method of ridding a patient of tenacious secretions and pseudo membranous *sloughs* Sometimes even this procedure is inadequate and an emergency tracheotomy is indicated It must be remembered that obstruction to respiratory exchange may be as great below the tracheotomy as above it but an opening in the trachea *facilitates* lavage and suction

CONGENITAL LARYNGEAL STRIDOR

In this condition there is an exaggeration of the *infantile* shape of the upper *aperture* of the larynx *the epiglottis is sharply* folded laterally the ary epiglottic folds are almost in contact and the opening is thus reduced *to a narrow* vertical slit As these parts are very flaccid in infancy they become sucked together during in spiration and by their vibration produce the characteristic stridor This stridor is noticed very soon after birth it is inspiratory of a *peculiar purring* or even musical character, and is most marked during active breathing *and crying The voice is* unaffected and there is remarkably little sign of dyspnœa or distress These char *acteristics distinguish the condition from other forms of obstruction* found in infants such as laryngeal web or papillomata or thymic asthma Symptoms tend to disappear during the second year of life but the prognosis must be guarded in early infancy for an attack of bronchitis is more than o *dinarily* dangerous and kills a proportion of these patients

LARYNGISMUS STRIDULUS

Ætiology —This is a condition clinically similar to glottic spasm occurring in children It is far commoner than the spasm of adults and it has been suggested that the asphyxial attacks of laryngismus are caused by collapse of the soft and yielding cartilaginous framework of the larynx and not solely by spasm of the muscles It is commonest between the ages of 6 months and 2 years but may persist later it occurs in ill nourished unhealthy children often in association with rickets and practically always in association with adenoids

Symptoms —The onset is sudden and attacks usually occur at night The child wakes gasping for breath and a series of short noisy inspirations is followed by complete cessation of breathing a long crowing inspiration terminates the attack There are retraction of the lower ribs and epigastrium cyanosis and great terror and distress and in severe cases carpo pedal contractions convulsions and evacuation of urine and fæces When the attack is over the child is perfectly normal and there is no hoarseness Slighter and less typical attacks often occur

Diagnosis —This is easy if the symptoms are carefully noted the sudden attack of dyspnœa with complete absence of symptoms in the intervals is quite distinctive

Prognosis —The prognosis is somewhat grave in severe cases an infant rarely dies in an attack but is often worn out and eventually succumbs to collapse of the lungs

Treatment —During the attacks the face and chest may be freely sponged with cold water and the inhalation of amyl nitrite from a capsule broken in a handkerchief may be tried The child should be supported sitting up and the quickest relief can usually be obtained by drawing the tongue forward with a finger passed into the mouth to its base a manœuvre easily performed by the mother or nurse The attacks are so short and sharp that there is no time for the hot bath or administration of bromides frequently recommended

Prevention involves the control of rickets with vitamin D fresh air wholesome food and correction of digestive disturbances Attention should be given to eliminating infection in the nose and drops of protargol 2½ per cent , may be instilled when the child is in the head down position It is particularly important to remove adenoids even if they are only moderately enlarged

CHRONIC LARYNGITIS

Ætiology —The causation is similar to that of acute catarrhal laryngitis indeed chronic laryngitis is often the result of recurrent acute attacks The principal factors which predispose to chronicity are nasal obstructions and discharges dental infections and chronic tonsillar sepsis dusty occupations and lack of fresh air over use of the voice and faulty voice production and the abuse of alcohol or tobacco consumptives are particularly liable to non specific catarrhal laryngitis Almost any cause of general ill health may be included among the predisposing causes

Symptoms —The only constant symptom is impairment of the voice which is hoarse easily tired or rarely almost completely lost It is sometimes weakest when tired in the evening but is often at its worst on rising in the morning or after a rest There is frequently a sensation of aching dryness tickling or of a lump in the throat and there is usually some cough but little expectoration unless the trachea and bronchi are involved

The objective appearances vary with the severity of the affection The larynx generally is of a deeper red than usual and the vocal cords have lost their normal pearly lustre and are pink they are usually somewhat thickened at the edges and enlarged vessels may be visible on their surface the vocal processes are often prominent and may be reddened or show up white against the hyperæmic cord Strings

of sticky secretion may stretch between the cords or a little globule of mucus may form on the centre of the cord during phonation, adduction is frequently imperfect When the epiglottis is reddened, its yellow edge stands out clearly and enlarged vessels are visible the ventricular bands are often swollen so as to hide the outer part of the cords The mucous membrane in the inter arytenoid space is seen to be thrown into folds on adduction of the cords and may form a mass large enough to prevent their complete approximation The general picture is one of symmetry a useful point in diagnosis when tuberculous laryngitis is in question

A patient suffering from atrophic rhinitis may develop an unusual form of chronic laryngitis known as *laryngitis sicca*, in which small brown scabs adhere to the cords and posterior commissure, but occasionally the disease itself spreads to the larynx which is covered by large greenish or brownish black fetid crusts, more rarely still the crusts extend into the trachea and cause severe dyspnœa

Pachydermia laryngis is an uncommon variety of chronic laryngitis occurring principally in middle aged men It is frequently ascribed to alcoholism, though perhaps on insufficient grounds and the diagnosis between pachydermia and tuberculosis or syphilis is often a matter of difficulty The characteristic epithelial thickenings are probably of the nature of corns resulting from frequent cough and continued irritation There is hoarseness of a rough raucous character, but no particular discomfort The epithelial thickening is pink or whitish and occupies the posterior region of the glottis from the vocal processes backwards to the posterior commissure A circumscribed swelling appears on each vocal process, with a small cup or depression at the apex the approximation of the cords is better than would be expected because the prominence on one vocal process fits into the depression at the other The epithelium of the inter arytenoid space is thrown into ridges which fill up the angles between the arytenoid and the posterior commissure but leave a depression in the middle line These firm opaque symmetrical swellings without ulceration are distinguishable from the soft irregular granulations of a tuberculous lesion

Treatment —The detection and correction of the ætiological factors are the most important part of treatment Any constitutional disturbance, such as anæmia rheumatism gout or dyspepsia should receive attention Over indulgence in tobacco or alcohol lack of ventilation and exposure to dust must be considered, and with teachers the blackboard chalk is a common source of irritation

Incorrect voice production is a factor of great importance and a good speech therapist can often provide substantial help

Almost always some infection is discovered in nose sinuses tonsils or teeth Elimination of such infection is the most important step in treatment

Locally treatment must begin with rest of the voice which should be absolute in the case of professional voice users Where there is much secretion a saline lotion may be used in a spray—sodium bicarbonate borax sodium chloride, gr 10 of each glycerin 60 min water to 1 oz Oily solutions are usually preferred such as menthol gr 5 camphor gr 2 chlorbutol gr 5 or oil of eucalyptus in similar proportions to 1 oz of liquid paraffin The direct application of pigments is not often called for and is to be recommended only when pachydermatous changes are present Dundas Grant advised an alcoholic solution of salicylic acid beginning with 1 per cent and increasing to 6 or 8 per cent

Internally small doses of potassium iodide, gr 2 or 3 three times a day over long periods is of value

TUBERCULOUS LARYNGITIS

Ætiology —In all cases the disease is secondary to pulmonary tuberculosis, of which it is an important complication It is probably caused by infection from the

sputum, is commoner in men than in women and is most frequent between the ages of 20 and 40 St Clair Thomson found that the difference in sex incidence is occupational and that women working in office and factory are as susceptible as men

Symptoms —The disease attacks in order of frequency the vocal cords arytenoid region inter arytenoid space ventricular bands and epiglottis in general the glottis is invaded before its upper aperture The typical infiltration is finely nodular pallid and soft in appearance ulcers are shallow with a smooth speckly base and pale ill defined margin On the vocal cord the disease chiefly attacks the posterior half and especially the vocal process where ulceration readily reaches the underlying cartilage and may produce a deep triangular excavation Thickening in the inter arytenoid region is common infiltration of the ary epiglottic folds results in typical pale semi translucent flask shaped swellings while the epiglottis appears as a firmer red sausage shaped mass

The voice is weak and has not the raucous quality associated with syphilis Sometimes voice production is actually painful Cough and expectoration are mostly due to the pulmonary disease and not in any considerable degree to the larynx Pain on swallowing is common and often very intense there may also be actual obstruction to deglutition and in a late stage entry of food into the larynx Dyspnœa is rare

Diagnosis —Although signs of pulmonary tuberculosis are helpful in diagnosis it is obvious that any kind of laryngeal disease may occur in a consumptive patient

From simple laryngitis —In the earliest stage of invasion tuberculous laryngitis may exactly resemble catarrhal laryngitis but redness of one cord only is certainly not due to catarrh and the latter quickly improves under treatment Inter arytenoid infiltration resembles pachydermia but the latter is opaquely white firm and symmetrical

From lupus typical tuberculosis differs completely The former is painless affects first the epiglottis and upper aperture is never accompanied by œdema and tends to cicatrisation But there is a chronic lupoid form of tuberculous laryngitis which attacks the epiglottis and is very similar to lupus

From syphilis —The tuberculous ulcer has an ill defined margin without surrounding hyperæmia the base has a yellow speckled appearance and on healing there is little scarring or contraction The superficial syphilitic ulcer has a well defined hyperæmic margin with a smooth flat base the deep ulcer is crateriform with thickened punched out edge and on healing leaves a dense scar and marked deformity In general syphilitic lesions attack the anterior half of the larynx tuberculous the posterior the former look firm and dense the latter soft translucent and ill defined

From neoplasms —Only the rare tuberculomata resemble innocent tumours Occasionally tuberculosis attacks one vocal cord in an elderly patient and may then easily be mistaken for epithelioma especially when as often happens in such cases, the pulmonary signs are inconclusive and tubercle bacilli absent from the sputum

Prognosis —This has greatly improved in recent years due to advances in the chemotherapy of tuberculosis

Treatment —Tuberculous laryngitis is but a complication of pulmonary tuberculosis and by far the most important part of the treatment is that of the general infection Complete vocal rest has in the past been the mainstay of treatment this is a severe and depressing measure and it is now not always necessary to enforce complete silence Streptomycin combined with isoniazid or sodium aminosalicylate (P A S) not only promotes healing of laryngeal lesions but within a very short time abolishes pain and dysphagia It should now never be necessary to use a galvano cautery or to insufflate analgesic powders let alone to inject alcohol around the internal laryngeal nerve In these days one no longer sees the desperate case of tuberculous

laryngitis in which the airway becomes obstructed and tracheotomy is called for There have, however, been rare cases of cicatricial stenosis following 'successful" chemotherapy

PARALYSIS

Paralysis of a vocal cord occurs in association with various diseases of the thorax and of the nervous system The early form unilateral abductor paralysis, causes no symptoms and can only be recognised by laryngoscopic examination

The original function of the laryngeal muscles is that of a sphincter to prevent the entrance of fluid into the lungs, and this sphincter or adductor, is the only muscle present in the larynx of primitive air breathing animals the abductors are a later addition In progressive lesions involving the nerve pathways the abductor muscles are first affected whilst the adductors continue to function for a variable time The function of phonation, much more recently acquired is associated with adduction and is under direct control of the will Functional disturbances therefore always cause adductor paralysis, while organic lesions first affect the movement of abduction

ORGANIC PARALYSIS

The crico thyroid muscle is supplied by the superior laryngeal nerve, and when this is injured the affected cord remains slack on phonation but owing to the short course of the nerve isolated paralysis of this muscle is extremely rare it results from surgical or suicidal wounds, and may occur after diphtheria In lesions of the vagus above the origin of this branch the signs of this paralysis are obscured by that of the other muscles of the cord The recurrent laryngeal nerves supply all the other muscles In any progressive lesion of the nerve pathway the muscles become paralysed in a definite order the abductors are first affected then the internal tensors or thyro arytenoidei and finally the adductors This is known as Semon s Law

There is but one muscle on each side which acts as an abductor of the vocal cord namely the crico arytenoideus posticus (often for convenience alluded to as the posticus muscle) This muscle not only moves the vocal cord away from the mid line during respiration, but its most posterior fibres brace back the arytenoid cartilage and stretch the aryepiglottic fold The cartilage of Wrisberg is incorporated in the fold and helps keep it taut in an upright position Thus it is that in ' posticus paralysis the aryepiglottic fold droops inwards and the cartilage of Wrisberg tilts forwards and inwards with it Yet another thing happens the arytenoid cartilage is free to slide and tilt forwards so that the cord appears shortened and tends to lie at a slightly lower level This forward tilting and apparent prominence of Wrisberg s cartilage is of help in diagnosis

ABDUCTOR PARALYSIS

The affected cord lies immobile in the midline, being held there by the unopposed action of adductor muscles (crico arytenoideus lateralis and inter arytenoideus) On phonation the unaffected cord swings over to meet its immobile fellow so that the voice is unaltered It is not quite true to say that during phonation the larynx appears normal for on the sound side Wrisberg s cartilage seems to move forward in front of its fellow The glottic aperture is reduced but dyspnœa is only noticed on exertion

Bilateral abductor paralysis is a serious condition particularly if the onset is sudden as both cords lie together in the middle line leaving a mere chink Inspiratory

embarrassment is extreme but the conical shape of the subglottic region allows expired air to blow the glottis open The voice is quite good, though the patient must constantly pause in a vain attempt to fill the lungs Were it not for forward displacement of the arytenoid cartilages referred to above thus allowing a chink patients would asphyxiate

COMPLETE PARALYSIS

When only the recurrent laryngeal nerve is involved the affected cord assumes a ' paramedian position for the crico thyroid muscle an external tensor and weak adductor is still acting The cadaveric or intermediate position can only be assumed when this muscle also is paralysed as in a lesion of the main vagus trunk above the superior laryngeal nerve from which it derives its innervation The true cadaveric or intermediate position is half way between abduction and adduction whereas the paramedian position is somewhat nearer the midline Few observers could distinguish such a small positional difference were it not for the fact that when the crico thyroid muscle is acting there is still some cord tension and when paralysed tension is absent so that the cord presents a wavy appearance The affected cord during respiration appears shorter and lies at a slightly lower level and the cartilage of Wrisberg seems unduly prominent The reasons have already been given when discussing the effects of posticus paralysis

In a unilateral case whether the lesion is true recurrent nerve palsy or high vagus palsy there is at first inefficient closure of the glottis and a feeble husky voice results air waste on phonation is characteristic As time goes on the voice may improve because the unaffected cord compensates and swings right across the midline on phonation At first there may be some overflow of water or food into the trachea but this also improves as time goes on

When complete paralysis is bilateral there can be no hope of efficient glottic closure The voice is feeble and breathy whilst spilling over into the trachea is a constant source of worry Breathlessness is usually only evident on exertion Bilateral complete paralysis is fortunately very rare

Diagnosis —The diagnosis is almost entirely a matter of accurate inspection Obliquity of the laryngoscopic image due to faulty position of the mirror may cause confusion In nervous subjects the cords are sometimes adducted on inspiration but they will abduct naturally during the involuntary inspiration which follows a prolonged phonation The only condition which really imitates paralysis is the fixation of the arytenoid cartilage which results from disease in or around the joint its complete immobility with the presence of swelling or scarring often aids the diagnosis but in old standing cases of paralysis secondary fixation frequently occurs In cases of arytenoid fixation there is no dropping forward of the cartilage of Wrisberg

Ætiology —The movements of the cords are represented bilaterally in the cortex cerebri and stimulation of either centre produces movement (adduction) of both cords from which it follows that no unilateral lesion above the bulbar nuclei can paralyse the larynx and clinically we find that it is never affected in cases of hemiplegia The bulbar centres lie in the floor of the fourth ventricle and here a lesion of one centre causes paralysis of the cord on the same side which in a gradually progressive lesion affects first the abductor muscle Thence the nerve fibres pass in the roots of the bulbar accessory to the vagus and recurrent laryngeal nerve the cause of the paralysis may therefore be situated (1) in the medulla (2) at the base of the skull (3) in the vagus or (4) in the recurrent laryngeal nerve

Paralyses of bulbar origin are often but by no means always bilateral In lesions here and at the base of the skull neighbouring nerves are liable to be involved thus paralysis of a cord and of the palate on the same side may coexist (syndrome of Avellis) or paralysis of cord palate trapezius and sternomastoid from involvement of the

spinal accessory roots or persistent tachycardia due to damage of the cardio inhibitory centre or nerves Tabes dorsalis is the most frequent cause of paralysis of central origin it may effect one or both cords and may be associated with anæsthesia paræsthesia or the spasmodic attacks called laryngeal crises In general paralysis of the insane laryngeal palsy is not uncommon It is the rule in bulbar paralysis and is usually bilateral, but appears late in the disease Syphilitic nuclear disease pachymeningitis and gummata at the base of the brain are now rare causes, and here the ocular muscles especially the external rectus, are often attacked

Peripheral causes usually act by compression of the recurrent nerve the most frequent being aneurysm enlarged glands, tuberculous or malignant, and cancer of the œsophagus Other causes are thyroid tumours, usually but not necessarily malignant, mediastinal tumours cancer of the lung pleurisy and pulmonary tuberculosis in which the nerve, usually the right, may be involved in a lesion at the apex of the lung or by tuberculous bronchial or tracheal glands Neuritis is a cause of laryngeal paralysis, it may be produced by the toxins of diphtheria or by organic poisons, especially lead and more rarely arsenic and alcohol Finally, the condition is not uncommonly the result of trauma more especially surgical operations on the thyroid gland and lung

Prognosis —Paralysis of one cord is not in itself dangerous to life, but when the cause is undiscovered the prognosis must be guarded, for this paralysis may be for a long time the only sign of serious disease, on the other hand, the recurrent laryngeal nerve may be involved in some non-progressive lesion such as a fibrotic bronchial gland and such cases have been under observation for 20 or 30 years without change

Treatment —This depends on the cause In most cases it is but a symptom of disease elsewhere and does not call for special treatment In cases due to neuritis strychnine and the local application of the faradic current by means of an intra laryngeal electrode are indicated Tracheotomy is advisable in bilateral abductor paralysis A specially designed tube in which a valve is incorporated is used, this valve allows air to enter freely on inspiration but closes during expiration so that the voice remains unaffected Operations devised to fix one arytenoid cartilage and vocal cord in a more lateral position sometimes give satisfactory results

All patients suffering from laryngeal paralysis must be forbidden to swim

FUNCTIONAL PARALYSIS (FUNCTIONAL APHONIA)

Ætiology —Functional aphonia is a common manifestation of hysteria and occurs chiefly in young women Many cases were encountered amongst men during the War of 1914–1918 and the War of 1939–1945 men whose terrifying experiences had driven them into a state of battle exhaustion Anæmia debility and local inflammatory conditions may predispose to an attack of aphonia but it seems clear that the condition would not materialise without some hysterical background It is true that some women are rendered aphonic by acute laryngitis of moderate severity but it is not the inflammatory process which prohibits cord approximation

Symptoms —Paralysis of the adductors presents a totally different clinical picture from organic paralysis It is always bilateral the larynx appears normal while at rest but on attempts at phonation it is seen that the cords do not adduct into the position necessary for the production of the voice Occasionally the internal tensors alone are working inefficiently an elliptical chink is left between the cords anteriorly If the crico arytenoidei laterales are paretic the entire glottis remains open to a variable extent and, very rarely the arytenoideus is affected alone when a triangular aperture is left behind the vocal processes The paralysis is hardly ever complete, indeed a considerable amount of movement is usually seen though insufficient to produce phonation In purely hysterical cases onset and recovery are sudden and

the voice when regained is clear though perhaps at first less powerful than usual Whilst examining the larynx through a mirror it is well to ask the patient to cough if the cords remain separated during attempted phonation and come together on coughing the diagnosis of functional aphonia is not in doubt

When a patient assailed by some great emotional disturbance is ' struck dumb ', she is not even able to whisper for the whole speech mechanism is paralysed This is called hysterical mutism

Treatment—In patients suffering from debility the cause should be found and treated Predisposing local inflammatory conditions should be sought for and appro priately treated It is well to remember that patients suffering from chronic phthisis sometimes speak very softly and may become almost aphonic

Although in some cases of true functional aphonia the voice can be temporarily restored by powerful local stimulation this form of treatment is not recommended for aphonia will usually recur The most difficult patients to treat are those who have been unsuccessfully subjected to such local treatment.

The physician must be sympathetic yet firm and confident and it is his first duty to explain that there is no serious disease The patient may be told that the trouble results from muscular inco-ordination

The best long term results are obtained when the voice can be restored during the first interview and it is imperative that no relation or friend should be in the room A good plan is to suggest that one group of muscles in the larynx is in spasm and that without complete body relaxation it is difficult to break down this spasm The patient may be asked to lie on a comfortable couch and told to relax as though about to go to sleep It is surprising how many patients will in fact go straight into a semi hypnotic state The laryngeal box may be moved from side to side across the vertebral column and suggestions made that by breaking down the spasm in this way the voice will be fully restored More often than not when told to rouse herself and recite God Save the Queen the patient will do so in a normal voice Should the voice be not fully restored the physician must retain his attitude of complete confidence and assure his patient that there has been encouraging improvement, and that restora tion of normal function can and will be attained in a short space of time When the voice is restored it should be freely exercised Really difficult cases must be referred to an expert for psychiatric treatment.

SPASMODIC AFFECTIONS

SPASM OF THE GLOTTIS

Spasm of the laryngeal muscles produces adduction of the cords for though the abductors are probably affected they are overpowered by the stronger adductor muscles

Ætiology—(1) In the majority of cases the spasm is a reflex set up by local irritation foreign bodies including the laryngoscopic mirror irritating gases and inflammation ulceration or tumours in or near the larynx (2) Spasm is also caused by irritation of the recurrent laryngeal nerves by mediastinal tumours and especially by aneurysm (3) Central nervous lesions especially tabes (4) Functional disturbances frequently hysterical and sometimes excited by sexual disturbances

Symptoms—The attacks vary much in different subjects in severity and duration The patient clutches some support or rushes to the window The respirations are rapid and shallow with loud inspiratory stridor and in the height of a severe attack, are completely arrested with all the signs of asphyxia The subjective sensations include a horrible feeling of anxiety but consciousness is not lost Many cases are less acute but persist longer even for several hours

Prognosis—The attacks are practically never fatal, unless a foreign body or tumour be present

Treatment—During the attack amyl nitrite or chloroform may be inhaled and ampoules of these drugs should be kept at hand Between the attacks sources of irritation should be sought for and removed, the upper air passages brought to a healthy condition and the general health and mode of life should receive attention Administration of bromides may be required when the attacks recur frequently

W I DAGGETT

DISEASES OF THE TRACHEA

INFLAMMATION OR TRACHEITIS

ACUTE TRACHEITIS

Acute tracheitis may occur from any condition leading to irritation of the mucous membrane of the trachea When it occurs as a result of bacterial or chemical agency the whole of the upper air passages are usually involved in greater or less degree, and the clinical manifestations are not confined to the trachea In some cases however, the stress of the resultant reaction falls upon this tube, and the condition therefore requires separate consideration

Ætiology—1 *Microbic invasion*—This is the commonest cause The bacteria usually found associated with tracheitis are the so called catarrhal organisms such as *Neisseria catarrhalis* the pneumococcus the Friedlander pneumo bacillus and *Hæmophilus influenzæ* It is probable that the primary organism in many cases is a virus Frequently a streptococcus may be found, either alone or in association with one or more of those just mentioned As with catarrhal inflammation of other parts of the upper air-passages damp, cold or foggy climatic conditions predispose to tracheitis It is more common in young and middle aged adults than in infancy or in old age Mouth breathers are more liable to this condition Exposure to sudden changes of temperature may be a factor in its onset

Tracheitis may also occur as part of the clinical picture in some of the acute specific diseases such as enteric fever, diphtheria whooping cough and measles It is often a troublesome and distressing association or sequel of true influenza

2 *Chemical agencies*—Irritating or poisonous fumes and vapours may lead to a very acute form of tracheitis It may therefore occur in certain occupations unless adequate precautions are taken The use of poison gases in warfare has drawn widespread attention to this form of the condition since tracheitis was an almost constant result of certain forms of gassing The chief chemical irritants used in the War of 1914–1918 were chlorine phosgene and dichlordiethyl sulphide commonly known as mustard gas Of these the last was perhaps the most irritant to the trachea and fatal cases invariably showed tracheal lesions Direct inhalation of steam may also induce an acute tracheitis

3 *Mechanical causes*—The presence of a foreign body or the invasion of the trachea by extension from malignant growth in adjacent structures may lead to a local or even to a general tracheitis It is noteworthy however that the trachea is frequently spared in occupations involving the respiration of dusty air which leads to deposits in the lungs and bronchial glands with resulting pneumoconioses Although a coal miner s lungs are black yet his trachea may be practically normal

Pathology—The changes found in the trachea vary from simple catarrhal inflammation to intense destructive changes with ulceration and in some cases croupous

or membranous exudate In the catarrhal forms, the mucous membrane shows changes similar to those in bronchitis It is at first swollen red and dry the vessels running across the trachea being engorged and clearly visible Then owing to increased activity of the mucous glands excessive mucoid secretion occurs and the mucous membrane becomes moist, after which resolution may take place or the process may proceed to a muco purulent stage when the fluid on the membrane coheres to form yellowish or green tenacious pellets Occasionally numerous red blood cells are extruded and the tracheal exudate becomes streaked tinged or uniformly pinkish

In some inflammations such as those induced by poison gases or inhaled steam the mucous membrane may be intensely engorged and actual destruction may occur involving even the deeper structures and the cartilages so that greyish yellow sloughs result which on separation leave ulcers In diphtheria the characteristic false membrane composed of necrosing fibrin leucocytes and bacilli may be found loosely attached to the mucous membrane as in other localisations of this process It may be primary or secondary to faucial or laryngeal diphtheria either by direct extension or through diphtheritic infection of a tracheotomy wound

In influenza the pink appearance of the trachea is of such constancy in fatal cases that it has come to be regarded as one of the most characteristic post mortem changes found in this disease The bright injection generally involves the lower half of the trachea but it may occur along the whole length of this tube

In whooping cough the inflammatory reaction is usually less acute

In typhoid fever small ulcers may occasionally be found in the trachea similar to those occurring more commonly in the larynx

Symptoms —Acute catarrhal tracheitis usually begins more or less acutely like the common cold of which it is to be regarded as one form with malaise slight headache and a mild degree of fever the temperature being usually between 99 and 100 F rarely 101 F The patient soon experiences a sensation of irritation behind the sternum rapidly leading to a harsh dry cough of noisy character The cough aggravates the retrosternal discomfort which develops into a sensation of rawness or soreness making the cough very painful and distressing If the larynx is involved at the same time the voice becomes hoarse and sometimes lost or reduced to a raucous whisper In tracheitis alone the voice is usually unaffected After from 12 to 24 hours the condition passes into the mucoid stage The cough becomes looser and less painful and small pellets of tenacious mucus are coughed up usually greyish or black in town dwellers whitish in those in rural conditions in either case the mucus may be streaked with blood or even tinged a uniform pink colour in the more acute forms it sometimes becomes yellow and more purulent In the mucoid stage the retrosternal soreness becomes less the constitutional symptoms abate while the temperature subsides and becomes subnormal The patient often feels weak and out of health for some days and is sometimes left with a noisy morning cough and tracheal irritation which may last for days or weeks The aspect of the patient shows nothing characteristic There is the general appearance of fever malaise and discomfort The rise of temperature and increase in pulse rate are usually moderate In the early stages physical examination of the chest shows no abnormality but when exudation occurs a coarse wheeze may be audible over the trachea particularly when the patient takes a deep breath or just before a cough occurs

Diagnosis —The association of catarrhal symptoms with a dry harsh cough and retrosternal soreness without signs of bronchitis is almost pathognomonic In some cases the diagnosis can be established with the laryngoscope or by endoscopy but in most the discomfort which these examinations entail is unnecessary

Prognosis —This is almost invariably good except in debilitated subjects or in those with cardiac or renal disease, in whom the process may spread to the larynx

bronchi or lungs The usual course is from 2 days to a week though cough and expectoration may persist for days or weeks The condition may become chronic To some extent the prognosis depends upon the care and treatment in the initial stage Cases that are neglected are liable to become chronic

Treatment —The prophylactic and remedial treatments of acute tracheitis are practically identical with that of acute bronchitis of the larger tubes Even in mild cases the patient should go to bed though this may be necessary only for 1 or 2 days but he should keep to his room till his temperature has become normal There may be less need for expectorants than in bronchitis, and a simple saline diaphoretic mixture with the addition later of tinct ipecac and tinct opii camphorata may be all that is necessary Sedative inhalations such as vapor benzoini are useful, and counter irritation to the sternal region is comforting to the patient When a chronic noisy cough develops a mixture containing small doses of apomorphine and tinct chloroform et morphin co often gives relief or codeine linctus B P C Penicillin is often of value given by inhalation or in severe cases by injection (pp 8 and 9)

When tracheitis occurs as part of some specific disease such as diphtheria or influenza the treatment should be that appropriate to the primary disease

In gassing ' every effort should be made to relieve the distressing and painful symptoms and for this purpose morphine may be required Various inhalations may be tried, and useless cough should be checked by sedative mixtures or by a linctus of heroin, morphine or codeine

CHRONIC TRACHEITIS

Ætiology —Chronic tracheitis may follow an acute attack, or it may develop insidiously in patients suffering from chronic laryngitis or bronchitis Inhalation of cigarette smoke is a not infrequent cause It is also sometimes a sequel of chronic rhinitis especially of the atrophic form or ozœna A certain degree of chronic tracheitis accompanies the specific lesions of syphilis and tuberculosis, which are described below

Pathology —Various degrees of chronic inflammatory lesions may be found In chronic catarrhal tracheitis the vessels are distended or engorged and the mucous membrane of the trachea becomes thickened and more or less covered with mucoid or muco purulent secretion the histological changes being those of chronic catarrhal inflammation namely shedding of the ciliated epithelial cells overactivity of the mucous glands and sometimes thickening and induration of the submucous tissues from proliferative changes A condition of perichondritis of the tracheal cartilages may, in this case, be observed and this may result in a mammillated appearance in the internal aspect of the trachea In ozœna, crusts similar to those in the nose and pharynx may form on the tracheal mucosa

Symptoms —The symptoms of chronic tracheitis are similar to those of the acute form There is a sense of discomfort and irritation about the trachea and a chronic almost dry cough often worse in the morning There is generally some scanty sticky expectoration mucoid or muco purulent, darkened by carbon particles and occasionally blood tinged

There are practically no physical signs of this condition except that the tracheal changes can be observed by the laryngoscope or by endoscopy of the trachea

Diagnosis —This is concerned chiefly with its differentiation from chronic changes in the trachea due to syphilis tuberculosis or leprosy and confirmation that it is not caused by the presence of new growth It must largely be made by endoscopic examination

Prognosis —The prognosis depends upon the cause When this can be removed as by treatment of predisposing conditions in the nose and throat, the outlook is good

When the tracheitis is due to other conditions such as syphilis and tuberculosis it depends upon the situation and extent of the other lesions and upon the treatment adopted

Treatment—This is in its main features similar to that of acute tracheitis but climatic treatment may be of great importance The patient may perhaps spend the winter months in a warm or equable and clear climate with great advantage When other conditions are concerned such as ozœna, syphilis or tuberculosis the treatment appropriate to them should be employed as well

CYSTS AND TUMOURS

These are rare conditions but require careful consideration

CYSTS

Owing to weakening of the wall of the trachea local bulging may occur giving rise to a cystic air containing swelling in the neck in direct communication with the lumen of the trachea Such cysts are known as tracheoceles or aeroceles They are resonant to percussion and can often be temporarily reduced by pressure

Small retention cysts may occur in the posterior wall of the trachea from obstruction of the ducts of the mucous glands as they pass through the trachealis muscle They are of pathological interest only and do not give rise to symptoms

SIMPLE TUMOURS

The most important is papilloma It occurs chiefly in children and is usually pedunculated When it grows in polypoid form it may lead to obstruction of the trachea low down in which case tracheotomy may fail to give relief and death results unless the tumour can be removed by endoscopic methods

Other innocent tumours occur but are rare They include enchondrosis from localised overgrowth of cartilage multiple enchondromata and osteoma from ossification of a pre existing enchondroma Lipoma and aberrant thyroid tumours may occur, but are very rare

Symptoms—These tumours produce varying degrees of tracheal obstruction and can usually only be recognised by endoscopy Treatment is considered under that of tracheal obstruction

MALIGNANT TUMOURS

A few cases of primary carcinoma of the trachea have been recorded Secondary growths are not common but the trachea is often involved and infiltrated by primary carcinoma in adjacent structures such as the œsophagus the bronchus the thyroid the larynx or by the extension of secondary deposits in the cervical or mediastinal glands

Primary sarcoma of the trachea is also very rare The growth is usually smooth and not pedunculated Secondary deposits of sarcoma in the trachea may occur from sarcoma of distant organs such as the kidney or it may be invaded directly by sarcoma originating in the thymus or other mediastinal structures and especially by lympho sarcoma of the mediastinal glands

Symptoms—The tracheal symptoms and signs are usually those of obstruction accompanied by pain When the primary growth is in the œsophagus antecedent

dysphagia and sometimes laryngeal paralysis reveal the origin of the tracheal symptoms when they occur In this case copious frothy mucoid expectoration is frequent, and when ulceration develops with perforation, food particles may enter the trachea excite cough and soon lead to inhalation broncho pneumonia or gangrene When the growth is near the bifurcation urgent dyspnœa is the rule, and spasmodic attacks may occur causing extreme distress In most cases of tracheal growth the characteristic clanging brassy cough (gander cough) of tracheal obstruction can be heard The trachea may be pushed to one side and its lumen distorted and obstructed by growth in the cervical glands or in the thyroid gland In mediastinal new growth invading the trachea, the pressure signs and symptoms characteristic of that disease usually render the explanation of the tracheal symptoms apparent

Diagnosis —Intratracheal growths have to be differentiated from other causes of tracheal obstruction, and the diagnosis is considered in detail under that condition Endoscopy affords valuable confirmation if it is practicable or desirable In œsophageal and mediastinal new-growths invading the trachea, radiographic examination may assist in diagnosis

Course —This is generally rapidly progressive

Prognosis —This is hopeless death occurring from asphyxia or from some complication or by asthenia

Treatment —Treatment can be palliative and symptomatic only In obstruction it may be possible in rare cases to give temporary relief by a low tracheotomy but, as a rule, this is impossible, owing to the presence of obstruction below any point where the trachea is accessible

THE INFECTIVE GRANULOMATA

SYPHILIS

The trachea may be affected in both the congenital and acquired forms

In congenital syphilis a progressive cicatrisation may occur leading to stenosis In acquired syphilis during the secondary stage the mucous membrane of the trachea may become generally hyperæmic or small raised mucous patches may develop locally In the tertiary period gummata may occur in the trachea, the commonest site being towards the lower end Degenerative processes leading to necrosis and softening eventually result in ulceration sometimes with local sloughing of parts of the tracheal rings In the process of cicatrisation a progressive stenosis may develop

Symptoms —Symptoms are those of chronic tracheitis and tracheal irritation in both the secondary and tertiary manifestations but in the latter, signs of tracheal stenosis may develop when scarring and healing are in progress Laryngeal involvement occurring at the same time tends to distract attention from the tracheal lesions or to obscure them

Diagnosis —The diagnosis of syphilis of the trachea depends upon a careful study of the history of the case indications of tracheal irritation laryngoscopic or endoscopic examination, the coexistence of other manifestations of syphilis and in their absence a positive Wassermann reaction

Prognosis —If the condition is recognised early excellent results may be obtained by treatment but it is obvious that where deep destructive changes have resulted, medicinal measures can only palliate

Treatment —Antisyphilitic treatment should be administered vigorously In cases of stenosis of the trachea from cicatrisation dilatation of the stricture by means of bougies introduced through an endoscope may be practicable and afford useful help

TUBERCULOSIS

Tuberculosis of the trachea may be found post mortem in advanced cases of pulmonary tuberculosis usually in those with extensive laryngeal involvement Primary tracheal tuberculosis is unknown Secondary lesions in the trachea and bronchi are found not infrequently on systematic endoscopic examination

Pathology —Tuberculous lesions may occur at any part of the trachea but they are more frequent in the lower part and on the posterior wall When they occur they are usually numerous There may be some general hyperæmia or small tubercles varying in size from a pin s head to a split pea may be visible Later superficial ulceration occurs forming irregular punched out ulcers Occasionally the process may extend deeper and erosion of the cartilages may occur with the formation of sinuses and even fistulous communication with the œsophagus

Symptoms —Since tracheal tuberculosis is usually a late manifestation of advanced disease its clinical indications are slight and are usually obscured by the more obvious laryngeal and pulmonary symptoms and signs though if the process extends deeply and produces sinuses and fistulous tracks it may become apparent The actual tracheal symptoms are those of cough and retrosternal soreness

Diagnosis —This condition has to be distinguished from other chronic tracheal lesions and a diagnosis can only be made from a careful review of the history the general evidence of tuberculous disease and by the tracheal involvement which may be visible by endoscopy

Treatment —American observers have treated the lesions by cauterisation with silver nitrate Streptomycin and isoniazid are usually effective

LEPROSY

In some cases of this disease, granulomatous lesions occur in the trachea and these may eventually give rise to tracheal stenosis owing to the contraction of new formed fibrous tissue The diagnosis can only be made from the occurrence of tracheal symptoms in a case with established lesions of leprosy in other parts

The treatment is symptomatic

SCLEROMA

Although in most cases this condition affects the nose only scleromatous lesions may be found in the trachea as a pathological curiosity The disease in any form is rare in England and occurs chiefly in Poland and Austria The nodules of granulomatous tissue in the trachea may cause partial obstruction mechanically or on contraction lead to actual stenosis

TRACHEAL OBSTRUCTION

Obstruction to the lumen of the trachea may be produced by foreign bodies by conditions originating in the trachea and by pressure from without

FOREIGN BODIES IN THE TRACHEA

The commonest route by which foreign bodies enter the trachea is through the mouth and larynx in the acts of breathing laughing yawning sighing or before and after coughing when food or some foreign substance is in the mouth A piece of bone a stud button false teeth chewing gum peas articles of food nuts grains of wheat, beads or blades of grass are among the substances which may gain entrance

to the trachea in this manner Surgical operations in the mouth and throat may lead to the inhalation of a tooth a piece of tonsil or a mass of adenoid tissue Material vomited from the stomach, such as food, blood clot or intestinal worms may be inhaled into the trachea A large blood clot in hæmoptysis may temporarily obstruct it Foreign bodies such as small projectiles embedded in old wounds of the neck peices of new growth or tuberculous glands may also gain access by ulceration through the tracheal wall

Unless it becomes impacted, or is too large to enter one of the two main bronchi a foreign body rarely remains long in the trachea It either causes death with dramatic rapidity is coughed out again, or passes down into one or other of the large bronchi or their secondary divisions, where it produces results which are described in the section on diseases of the bronchi

Symptoms —These depend upon the mode of entry the size of the foreign body, and the degree of obstruction to the air current which it induces but in general the tracheal symptoms are less urgent than those of laryngeal obstruction and less serious than those of obstruction of one or other main bronchus There may be intense dyspnœa with great discomfort and alarm during the actual passage through the larynx of a small foreign body especially if it is temporarily arrested there but when it enters the trachea there is an almost instantaneous cessation of the acute distress though some degree of dyspnœa may persist The type of dyspnœa is inspiratory in the main though a minor degree of expiratory difficulty may be apparent if the foreign body is of considerable size There may be a definite stridor with both phases of respiration, but it is more pronounced in inspiration If the foreign body remains loose in the trachea which may occur if it is rounded and too large to engage in one of the main bronchial divisions a sound of vibratory character may be heard on auscultation of the trachea sometimes described as the *bruit de grelottement* This may be produced by friction of the foreign body against the tracheal wall or more commonly by the air passing over it during respiration A paroxysmal cough may occur caused by the foreign body irritating the sensitive posterior wall of the trachea and during such an attack the foreign body may be forced up to the larynx obstruct it or cause reflex spasm with intense dyspnœa and cyanosis and a risk of suffocation unless it drops back is coughed out or removed When sudden rupture of caseous material into the trachea occurs the lumen may be blocked and death take place rapidly

Diagnosis —The history of disappearance of some object from the mouth during coughing breathing or laughing should give rise to suspicion of an inhaled foreign body and this may be confirmed by seeing the object directly by endoscopy or indirectly by means of the radiograph

Course —A foreign body impacted in the trachea may give rise to septic inflammation of its walls with subsequent cicatrisation after removal or it may lead to secondary infective processes in the lungs such as purulent bronchitis and bronchopneumonia

Prognosis —This depends in the main on the nature of the foreign body and the time elapsing before its removal An irregular rough or soft foreign body is more likely to induce septic complications than a smooth hard substance Apart from rapidly fatal results the prognosis is better with intratracheal foreign bodies than with those reaching the bronchi If removal is effected within 24 to 36 hours recovery is usually rapid and complete

Treatment —Treatment consists in rapid removal with as little damage to the trachea and larynx as possible This may be effected by means of forceps passed through a bronchoscope or rarely by tracheotomy alone when the foreign body may be coughed out through the opening or be easily removed by forceps Inversion of the patient in the hope that gravity may assist the expiratory efforts of cough is dangerous and should only be attempted after tracheotomy has been performed Where

rupture of a caseous gland or softening new growth occurs into the trachea an *immediate tracheotomy may be necessary*

OBSTRUCTION FROM CICATRISATION OF THE TRACHEAL WALLS

Ætiology —This may result from any condition leading to ulceration of the *tracheal walls with subsequent healing such as a syphilitic gumma or less commonly* other granulomata such as tubercle leprosy or scleroma Another cause is cicatrisation from wounds of the trachea accidental suicidal or after tracheotomy when the incision has been made too near the cricoid or when the wound has become infected or the tube left in too long Scarring from damage to the trachea by the inhalation of boiling or caustic liquids or even by inhaled gases may lead to stenosis

Pathology —The deformity of the trachea and the obstruction of its lumen depend upon the situation and the extent of the cicatricial contraction of its walls It may be local producing an hour glass constriction or involve a long extent of the tube Occasionally especially in syphilitic lesions stenosis may occur at two different levels

Symptoms —These depend upon the degree of stenosis the rapidity with which it develops and the condition of the larynx bronchi and lungs When the stenosis is produced gradually as in cicatrisation a degree of obstruction may result greater than would be compatible with life if suddenly induced In the early stages of a progressive stenosis slight dyspnœa may be present on exertion and during sleep a faint stridor may be audible disappearing when the patient is awake As the contraction progresses the dyspnœa becomes more marked and a definite and persistent stridor develops at first inspiratory only though expiration may become both noisy and obstructed The patient may experience a sensation of obstruction referred to the neck or under the sternum accompanied by pain and irritation leading to cough which may be dry noisy and metallic or accompanied by more or less frothy sputum if the primary condition is associated with widespread tracheitis The voice may lose tone and volume and the patient talk more quietly than normal and with some evident effort In advancing stenosis sudden and alarming attacks of dyspnœa may occur leading to cyanosis and threatening suffocation These attacks are usually due to an accumulation of mucus at the site of the stenosis The patient in advancing degrees of obstruction cannot lie down and generally sits leaning forward with chin depressed It may be noted that the extraordinary muscles of respiration contract forcibly and yet the laryngeal excursions may be small or hardly noticeable in contrast with those of laryngeal obstruction in which they are maximal This distinguishing sign was first pointed out by Gerhardt and is of value but unfortunately it is not absolute and cannot therefore be regarded as pathognomonic On auscultation over the trachea a noisy roar may be audible of maximum intensity near to the obstruction whereas the breath sounds over both lungs may be deficient although the stridor may be conducted bilaterally

Diagnosis —Tracheal obstruction from cicatrisation has to be distinguished from laryngeal obstruction in which the symptoms are usually more acute and more urgent Gerhardt s sign described above may also be suggestive It has also to be differentiated from obstruction due to pressure from without (*vide infra*) The only reliable method of distinction is by direct inspection with the bronchoscope

Course —The course of cicatricial stenosis is usually progressive unless arrested by treatment and the dyspnœic attacks become more frequent and alarming

Prognosis —Early syphilitic stenosis may be arrested by appropriate antisyphilitic treatment Obstruction due to other granulomatous conditions varies with the severity and extent of the primary lesions Caseous material or degenerated growth ulcerating

into the trachea is usually immediately fatal or leads to death within a few days from pulmonary complications

Treatment—*Rest should be advised with avoidance of exertion, smoking and alcohol* The patient's fears should be allayed and symptomatic treatment ordered such as sedative inhalations or a linctus to check useless cough In syphilitic stenosis vigorous antisyphilitic treatment should be given A low tracheotomy may be necessary for an intractable stricture high up in the trachea In some cases where an ordinary tracheotomy cannot be performed below the stricture it may be possible to insert Koenig's long tracheotomy tube through an opening in the trachea made above it In other cases dilatation of a fibrous stricture by bougies passed through an endoscope may be feasible

OBSTRUCTION FROM EXTERNAL PRESSURE

Pressure on the trachea may occur in the neck or in the mediastinum

Causes of pressure in the neck—Strangulation, throttling and garotting lead to death by occlusion of the trachea and suffocation *Enlargement of both lobes of the* thyroid body may cause lateral compression of the trachea, until eventually its lumen is reduced to a narrow slit—the so called 'scabbard trachea' Irregular or unilateral enlargements on the other hand cause deviation of the trachea with kinking of its lumen Other less common causes of compression of the trachea are enlargement of the cervical glands from tuberculosis malignant disease *Hodgkin's disease or leukæmia* The trachea may be pressed on from behind by a foreign body impacted in the œsophagus or by a bony tumour arising from the vertebræ

Causes of pressure in the mediastinum—An aneurysm of the aortic arch may press directly upon the trachea at or near the bifurcation and cause obstruction Similarly deep pressure may be caused by a retrosternal goitre a persistent and enlarged thymus, or a thymic abscess mediastinal glands enlarged from any cause, usually malignant disease, a dermoid cyst or a bony tumour originating in the sternum

Symptoms—The symptoms are in the main identical with those of stenosis of the *trachea from intrinsic causes with the special symptoms due to the primary* external condition superadded

Diagnosis—This may be simple and obvious, as in those cases due to pressure from tumours in the neck whereas in those due to mediastinal pressure it is usually only possible after a careful survey of all the symptoms and is in brief identical with that of aneurysm or mediastinal new growth to which reference should be made In some cases radiographic examination may give valuable information

Prognosis—This is good in obstruction due to causes in the neck other than malignant disease but it is grave almost hopeless in obstruction due to mediastinal *causes with the exception of abscess, goitre,* dermoid cyst and some thymic conditions

Treatment—The treatment is that of the primary condition In goitre and tuberculous glands in simple tumours cysts and some thymic condition operation may be possible and may effect complete cure In those due to mediastinal pressure, especially from aneurysm or new growth treatment in *most cases*, can be only palliative or symptomatic and directed to the relief of pain dyspnœa cough and distress

INJURY

Direct violence to the trachea has been known to cause rupture when the chin is raised upwards and the trachea is thereby extended

DISEASES OF THE BRONCHI

BRONCHITIS

Inflammation of the bronchi or bronchitis is one of the commonest maladies and may be induced by a variety of causes These, in the main fall into three groups bacterial chemical and mechanical similar to the causes of tracheitis which is indeed in many cases a concomitant or antecedent of bronchitis so that tracheo bronchitis would be a more accurate designation of the majority of cases At the same time it should be recognised that the trachea may be alone or predominantly affected while on the other hand in many cases of bronchitis of the smaller tubes the trachea may escape or be only slightly involved

Bronchitis is so varied in its extent and in the form and severity of its manifestations that a satisfactory classification is somewhat difficult to formulate We propose to consider the clinical manifestations of bronchitis according to the following classification

1 Acute Forms —(*a*) Catarrhal bronchitis (1) of the larger tubes (2) of the smaller tubes (*b*) suppurative (*c*) secondary bronchitis (*d*) bronchitis due to mechanical and chemical agencies (*e*) fibrinous

2 Chronic Forms—(*a*) Catarrhal (*b*) suppurative (*c*) secondary (*d*) due to mechanical agencies and (*e*) fibrinous

1 ACUTE BRONCHITIS

ACUTE CATARRHAL BRONCHITIS OF THE LARGER TUBES

Synonyms —This condition is often called Bronchial Catarrh or Acute Tracheo bronchitis

Ætiology —*Predisposing causes* —Climate undoubtedly plays an important part Catarrhal bronchitis is rare in polar and arctic regions and near the equator but is very prevalent in damp and foggy climates In England attacks are common in late autumn winter and early spring Owing chiefly to greater exposure the disease occurs more frequently in men than in women It is most common at the extremes of life infancy and old age but it is not infrequent at any age Fatigue and privation play their part and exposure to cold wet or fog so frequently seems to initiate the attack that it is often regarded as the exciting cause Scoliosis kypho scoliosis and other malformations or deformities of the chest predispose to bronchitis and some of them are induced or aggravated by bronchitis early in life Chronic cardiac and renal disease both render their subjects more liable to bronchitis as do also conditions of the nose and pharynx which lead to mouth breathing in consequence of the inhalation of air which is unwarmed and unfiltered by the nose There is a popular idea that a child may cut its teeth with bronchitis but the combination is probably coincidental

The exciting cause is not really known There is a suspicion that the infection is primarily viral in origin Pneumococci streptococci *Neisseria catarrhalis* staphylococci *Hæmophilus influenzæ* Friedlander s bacilli (*Kl pneumoniæ*) are found in the sputum or tissues but they are probably secondary invaders

Pathology —The changes induced in the bronchi are similar to those in the nasal mucosa in coryza and in the trachea in tracheitis Three stages may be described An initial dry stage when there is active hyperæmia of the bronchial mucosa with exudation into the submucous layer causing temporary diminution of the bronchial secretion from occlusion of the mucous ducts The second or mucoid stage is associated with copious discharge of mucoid secretion owing to increased

activity of the mucous glands this secretion being mixed with shed ciliated epithelial cells and scanty leucocytes Sometimes in acute cases a few red blood corpuscles are present The third stage is that of resolution though not infrequently a muco purulent stage occurs when the sputum becomes less copious and greenish in colour from large numbers of pus cells

In fatal cases the lung tissue may appear slightly distended and red while the bases may be sodden from œdema On section the bronchi appear injected and the mucosa is swollen On squeezing the lung beads of mucoid fluid or muco pus exude from the cut ends of the bronchi There is no consolidation and the lung tissue floats in water

Symptoms —An attack of acute bronchitis generally begins suddenly with *malaise, aching in the limbs and a sense of oppression in the chest* If the trachea is also involved, there is the characteristic feeling of rawness under the sternum The temperature rises, varying from 99° to 100° F in mild cases to 103° F in more severe ones The cough is at first dry irritating and ineffective but in a few hours it becomes looser The sputum in the early stage is scanty, tenacious and sometimes streaked with blood, it then becomes copious, mucoid and frothy in character, and is found to contain mucus, shed epithelial cells leucocytes and red blood corpuscles Later it lessens in quantity and may become thick yellow and muco purulent With the onset of expectoration there is generally an abatement in the symptoms the rawness under the sternum disappears and the feeling of pain or soreness about the pectoral muscles and the costal attachments of the diaphragm lessens The febrile reaction may last only 3 or 4 days but the cough and expectoration may go on for 10 days or longer gradually diminishing until they are present only night and morning and then cease completely

In the early stage the patient is flushed and the breathing may be slightly in creased in rate but it is rarely or never laboured unless emphysema coexists Vocal fremitus is unaltered but rhonchal fremitus may sometimes be felt over one lung or both The chief physical signs are discovered only on auscultation The breath sounds may be harsher and higher pitched particularly in infants and children but they remain vesicular and expiration may be prolonged The voice conduction is unaltered As a rule rhonchi either sonorous or sibilant according to the size of the bronchus in which they are produced are audible over both lungs, and during the mucoid stage bubbling rales may be heard especially at the bases

Complications and Sequelæ —Bronchitis may go on to broncho pneumonia lobar pneumonia aspiration pneumonia lobular atelectasis fibroid induration or bronchiectasis It may lead to chronic bronchitis or be followed by active tuber culosis Occasionally acute interstitial emphysema may result from violent coughing

Diagnosis —The diagnosis of bronchitis is usually easy owing to the character istic rhonchi but it is important to differentiate primary bronchitis from bronchitis *occurring as a secondary condition in acute specific fevers* and other diseases

Course —This is variable The patient may be convalescent in from 7 to 14 days but cough expectoration and a condition of debility may continue for several weeks though in this case the possibility of pulmonary tuberculosis should always be considered

Prognosis —Bronchitis of the larger tubes is rarely fatal except when it occurs in infants or the aged or as a complication of advanced cardiac or renal disease

Treatment —PROPHYLACTIC —This consists in the avoidance of stuffy ill venti lated rooms and places of entertainment when catarrhal infections are rife In mouth breathers, steps should be taken to deal with the conditions of the naso pharynx inducing this habit and instruction in normal breathing given In dusty occupa tions suitable measures should be taken to minimise the irritant particles in the air as is now done in most factories and workshops Where poisonous gases have to be encountered some form of efficient gas mask should be utilised

Vaccines have been and still are widely used in the prophylactic treatment of catarrhal infections They have their enthusiastic adherents amongst doctors and patients but there is no objective evidence of their efficiency and much to the contrary

CURATIVE —No matter how mild the attack may be at the onset the patient should be kept in bed This may only be necessary for 1 or 2 days but he should keep to his room till his temperature has returned to normal The room temperature should be kept at 60 to 65° F While the temperature is raised the diet should be simple adapted to the patient s appetite and the febrile condition The patient should take plenty of fluids and hot warm drinks are often welcome The air of the bedroom may be moistened by the use of a steam kettle in the dry stage but steam tents should not be used Hot compresses over the sternum sometimes help to relieve the raw soreness The inhalation of steam is comforting and vapor benzoini—60 minims to the pint of water at 160 F or vapor pini 120 minims to the pint—is often added to the water During the dry and painful period of acute bronchitis a sedative linctus may ge given Once expectoration starts mixtures containing ammonium chloride or carbonate combined with squills and flavoured with syrup of tolu or of Virginian prune may be given Sedatives may be necessary at night—Dover s powder gr 10 with or without aspirin barbitone gr 5 to 10 or chloral hydrate gr 10 to 20 are all suitable Opium and its derivatives are best avoided Antibiotics are not usually necessary or required although they may cut down the secondary infection and are often given as a routine to elderly patients The older the patient the longer should be the convalescence Premature return to normal life may be followed by a relapse or perpetuation of the bronchitis for weeks

When bronchitis occurs as a part of some specific disease such as diphtheria or influenza the treatment should be that appropriate to the particular disease

ACUTE CATARRHAL BRONCHITIS OF THE SMALLER TUBES

Synonym —Capillary Bronchitis

It is open to question whether this condition exists as a separate entity When the finer bronchi and bronchioles are inflamed the alveoli invariably become involved since very little swelling of the bronchiolar walls is sufficient to occlude the lumen of the tube with the inevitable production of an area of lobular collapse The transi tion from this condition to actual lobular pneumonia is a very small one In any case the causes the symptoms and the treatment of capillary bronchitis and broncho pneumonia are identical (see Broncho pneumonia)

ACUTE SUPPURATIVE BRONCHITIS

Synonyms —Sometimes called Acute Purulent Bronchitis

This condition was brought into prominence during the War of 1914–1918 In 1916 and 1917 it appeared in epidemic form amongst the British troops in England and France Although it was then regarded by some observers as a new disease it is more probable that it was in reality an epidemic form of a condition usually rare and sporadic and previously termed suffocative catarrh

Ætiology —*Predisposing causes* —The exceptionally severe winter of 1916-1917 together with conditions of overcrowding in huts and billets were undoubtedly concerned in the epidemic just mentioned The condition affects young adults chiefly and is much more common in men Over exertion fatigue and debility predispose to it but the disease may occur in robust and healthy persons A history of chill may be given but often no obvious cause can be discovered

Exciting cause —The organisms usually found are the pneumococcus and *H influenzæ* the latter being reported in 90 per cent in some series of cases *N catarrhalis* is also sometimes present

Pathology —A very intense inflammation occurs in the medium sized and small bronchi, leading to an exudate rich in leucocytes The inflammatory process may *extend to the alveoli which then contain a fibrinous fluid, with entangled red cells* The condition occurs in both lungs and is usually almost universal no portion being spared Post mortem the lungs are heavy and red in colour On section the bronchi are found to contain a thick yellow purulent fluid Small areas of collapse and some times of broncho pneumonic consolidation are seen, and there is usually œdema of the bases Plastic pleurisy is not infrequent and the glands at the root of the lungs are enlarged

Symptoms —*The onset is usually abrupt, often in young people apparently in* robust health A definite chill may occur, or only coryza and general malaise with aching of the muscles The temperature rises quickly and may reach 104° F early in the disease A cough soon develops and extreme dyspnœa is a characteristic feature Expectoration starts early, often on the second or third day At first it may be streaked with blood but it soon becomes yellowish green and nummular it consists of almost pure pus there is often as much as 5 or 6 oz in 24 hours In most instances there is great prostration *In grave cases the patient becomes unconscious and loses* control of the sphincters

There is intense cyanosis the face lips and ears being purple The respirations are rapid, 30 or 40 per minute, and the accessory muscles are often in full action Palpation and percussion may not show any abnormality though slight dullness is sometimes present at the bases At first no signs may be discovered on auscultation, but soon the breath sounds become largely obscured by medium sized bubbling rales often audible from apex to base both front and back The pulse is frequent the right heart may dilate and the heart sounds become weak

Complications and Sequelæ —In severe cases recurrent bronchitis broncho pneumonia fibroid disease or emphysema may follow

Diagnosis —*The early occurrence of marked dyspnœa and cyanosis* the expectoration of copious pus and the widespread rales without dullness are very suggestive of acute suppurative bronchitis The disease must be differentiated from other conditions described as acute suffocative catarrh that are associated with extreme dyspnœa and cyanosis

Acute pulmonary œdema is usually afebrile and the sputum is albuminous frothy and copious The condition leading to it such as cardiac or renal disease may be apparent

Capillary bronchitis or broncho pneumonia may give rise to difficulty but in these conditions the sputum is scanty tenacious sometimes rusty and but rarely purulent, moreover cyanosis and dyspnœa develop late and depend upon the extent *of the disease and the condition of the right side of the heart*

Pneumonia of the wandering type may simulate this condition but the character of the signs with dullness and tubular breathing and the rusty sputum usually render diagnosis easy

Course —*In favourable* cases complete restoration to health results In severe cases the course is rapid the patient becomes comatose from toxæmia expectoration ceases and death occurs from exhaustion in 2 or 3 days from the onset In other cases the disease may last for 6 weeks and proceed to recovery or death

Prognosis —This is very grave The mortality is high often as much as 50 per cent Cases extending to 3 weeks or more with swinging temperatures usually recover

Treatment —The disease is highly infectious and the patients should be isolated In the 1916 1917 and 1918 epidemics death occurred earliest and most frequently in those who walked about while infected Immediate rest in bed is essential and oxygen should be given from the beginning by double nasal catheter or B L B mask Penicillin or other suitable antibiotic as indicated by the sputum should be tried from the start

SECONDARY BRONCHITIS

Ætiology—Bronchitis usually of catarrhal type—indistinguishable as regards symptoms and sign from primary acute catarrhal bronchitis—occurs as a definite part of many acute infectious diseases and as a complication in others Among these may be mentioned measles whooping cough influenza the enteric group small pox diphtheria malaria and plague Acute nephritis of infective origin is often accompanied by acute bronchitis Other conditions associated with bronchitis are pulmonary tuberculosis glanders secondary syphilis pleurisy and gunshot wounds

Diagnosis—Bronchitis is easy to recognise but it is important not to overlook the fact that it may not be the primary condition In all cases of bronchitis in the early stages the possibility of a primary acute specific infection should be borne in mind The diagnosis is also of importance in regard to treatment—for example in malaria nephritis and syphilis in which treatment directed to the primary condition may be more helpful than the ordinary treatment of catarrhal bronchitis

BRONCHITIS DUE TO MECHANICAL AND CHEMICAL AGENCIES

Ætiology—*Mechanical*—Attacks of acute bronchitis may be caused by the inhalation of dust laden air In occupations where the worker is liable to inspire fine particles of carbon silica steel iron asbestos or kaolin acute bronchitis may result but more often these conditions lead to chronic bronchitis and pneumoconiosis Some industrial dusts are especially irritating manganese dioxide and basic slag and certain fine wood dusts from West Africa are examples of these

Chemical—Acute bronchitis may follow the inhalation of chemical irritants either as a result of occupation accidents attempts at suicide or the use of poison gases in warfare Special attention has been drawn to this subject by the large number of cases of gassing dealt with in the War of 1914–1918 Death not infrequently occurred much acute suffering was caused and some permanent damage has resulted in many cases which recovered Mustard gas produces its chief effects upon the skin the eyes and the bronchi A fibrinous exudate forms on the mucosa as a false membrane which separates as a slough The suffocative gases chlorine and phosgene affect the alveoli primarily and more intensely Chlorine inhaled in a concentration of 1 in 10 000 causes a rapid alveolar flooding with a serous and highly albuminous fluid and if the victim does not die at once he is liable to suffer from an acute bronchitis A condition called bronchiolitis fibrosa obliterans may occur as a sequel It is often associated with asthmatic dyspnœa Lewisite produces much the same effect on the lungs as mustard gas The only noxious gases likely to be met with in civilian life are nitrous fumes chlorine and ammonia

Symptoms—These are similar to those of acute catarrhal bronchitis but there is great pain distress and almost constant cough often with copious expectoration

The treatment is referred to under the heading of Tracheitis and is in the main symptomatic and directed to the relief of pain useless cough and distress If there is cyanosis oxygen should be given continuously if necessary by double nasal catheter B L B mask or oxygen tent

ACUTE FIBRINOUS BRONCHITIS

Synonym—Acute Plastic Bronchitis

Definition—A comparatively rare acute disease in which there is inflammation of the bronchi with the formation of casts These may be hollow or solid and are coughed up in the expectoration

There are some who deny that this is a disease *sui generis* and who maintain that it is but a condition found occasionally in bronchitis It appears to have been known to the ancients and in more recent times was well described by Osler and McCrae and more recently by Davidson Both these accounts describe it as a separate entity

Ætiology—It is more common in males and is met with both in children and

in adults It may begin as a primary catarrhal bronchitis or develop as a complication of enteric fever, measles or pulmonary tuberculosis Such organisms as the pneumococcus or a streptococcus may be found in the casts

Pathology —The casts may involve the main bronchi only, or more frequently the smaller ones and the bronchioles They are greyish white solid or tubular and when large, bear the impress upon their exterior of the bronchial walls in which they have been enclosed Thus when a cast extends up to the lower portion of the trachea, the indentations made by the tracheal rings may be seen impressed upon it The fine terminations generally show a spiral moulding Chemically they consist of fibrin or of fibrin and mucin Post mortem the casts may be seen in some places *in situ* in other areas the bronchi from which they have been expelled may be recognised The bronchial mucous membrane is at times acutely inflamed, red in colour with the lining epithelial cells desquamating or it may appear pale and unaffected There is usually a certain degree of emphysema and there may be collapse of lung tissue beyond the site of obstruction

Symptoms —The disease generally begins somewhat abruptly with a cough and malaise In the course of a few days the patient becomes considerably worse, dyspnœa develops and a certain degree of pyrexia but the temperature is often not more than 99° or 100 F The dyspnœa becomes more intense and is the prominent and all important symptom The face is seen to be cyanosed the alæ nasi and the accessory respiratory muscles are in violent action, sometimes with retraction of the intercostal spaces There may be diminished movement of the chest either bilateral or unilateral If there is unilateral pulmonary collapse the heart may be slightly displaced towards the same side Vocal fremitus may be normal or locally diminished The percussion note is somewhat hyper resonant over the anterior chest wall, but behind there may be some degree of dullness over one or other lobes If the bronchi are unilaterally affected there may be dullness limited to one lower lobe with diminution of air entry and no adventitious sounds Vocal resonance over the affected area is lessened There is usually some diffuse bronchitis as indicated by the presence of rhonchi or rales Marked stridor is sometimes heard with respiration A special sign the bruit de drapeau has been described when the cast lies free in the bronchial lumen It is a dry clicking sound caused by the flapping of the cast against the wall of the bronchus as the air passes over it The ordinary sputum does not show any peculiarities It may however show Curschmann s spirals Charcot Leyden crystals and eosinophil cells and it may be absent until the crisis occurs This consists in the expectoration of the cast after a violet fit of coughing The cast may be stained with blood or there is sometimes actual hæmoptysis The peculiar nature of the expectoration often escapes notice unless it is examined by floating in water when a large intact cast is revealed The dyspnœa ceases immediately after the cast has been expelled

Complications and Sequelæ —Emphysema may occur as the result of the violent coughing or the disease may become chronic recurring at intervals of varying duration The most serious complication is laryngeal obstruction caused by the cast becoming impacted between the vocal cords

Diagnosis —The stridor and respiratory obstruction are suggestive of œdema of the glottis but auscultation will show that the site of the lesion is lower down the respiratory tract Asthma and all causes of laryngeal and tracheal obstruction must be excluded The dyspnœa and the presence of signs localised to one lobe may suggest an active lobar collapse or a lobar pneumonia but the dyspnœa is more intense than is met with in either of these conditions Casts are expectorated in diphtheria pneumonia chronic disease of the heart pulmonary tuberculosis and hæmoptysis The casts of acute fibrinous bronchitis are firmer than those found in these affections and are expectorated in long pieces showing the many branches and bifurcations of the bronchial tree

Course—The disease is generally self limited terminating with the separation and expectoration of the cast The acute stage does not as a rule continue for more than 12 to 24 hours

Prognosis—The immediate outlook is fair Death may occur in the first attack or recurrences may take place which lead to an increasing degree of emphysema with its usual results The ultimate prognosis is therefore not good

Treatment—The patient should be kept in bed and treated as a case of acute bronchitis Inhalations of medicated vapours often afford relief Potassium iodide is believed to expedite the separation of the cast Bronchoscopic removal is sometimes necessary and tracheotomy instruments should be available in case of laryngeal obstruction

2 CHRONIC BRONCHITIS

Chronic bronchitis is perhaps even more difficult to classify than the acute varieties each one of which may have its counterpart in chronic form so that the same classification may be followed At the same time it must be admitted that especially in the catarrhal forms the clinical manifestations are somewhat varied

CHRONIC CATARRHAL BRONCHITIS

Ætiology—The causes are practically identical with those of the acute form of which it is in most cases a sequel

This affection may commence at any age although it is more common in middle life and with advancing years Men are more frequently affected than women It seems also to have a special incidence in some families It is more common in damp and foggy climates and is favoured by urban conditions and by dusty occupations It starts each winter with a more or less acute catarrhal attack but each year the summer intermission becomes shorter until the bronchitis persists throughout the year It tends to produce emphysema and is aggravated in turn by this condition It is especially favoured by cardiovascular lesions such as valvular defects and arterial disease also by gout chronic nephritis syphilis and alcoholism Conditions associated with chronic cough predispose to it notably emphysema asthma arrested pulmonary tuberculosis mouth breathing and cigarette smoke inhaling

The bacteria found are practically identical with those in acute bronchitis the commonest being the pneumococcus Friedlander s pneumobacillus *N catarrhalis* streptococci and staphylococci Mixtures of two or more of these may be present

Pathology—The bronchi show chronic inflammatory changes of a catarrhal nature The walls are thickened from chronic hyperæmia and also from productive changes in the connective tissues The mucous glands may be hypertrophied or atrophied and there may be widespread desquamation of the ciliated epithelial lining of the bronchi In long standing cases there is usually some peribronchitis leading to cylindrical bronchiectasis and distortion of the bronchi by fibrosis There is almost invariably a greater or less degree of emphysema which may be generalised or only marginal Post mortem the lungs are generally red and somewhat engorged but if much emphysema has resulted they may be paler than normal On squeezing the lung after section pus or muco pus exudes from the cut bronchi and there is usually some evidence of œdema at the bases

Symptoms—A patient with chronic bronchitis complains of cough expectoration and shortness of breath on exertion The cough varies greatly in its severity During the warm weather the patient may be completely free and yet suffer for years from a winter cough It may occur frequently throughout the day and in attacks at night or only in the mornings and evenings

The expectoration varies considerably in quality and quantity so much so that

the old classifications of chronic bronchitis were based on this factor Thus there may be practically no sputum or only small tenacious pellets the ' crachats perlés of Laennec on the other hand there may be a profuse expectoration resembling unboiled white of egg diluted with water Usually the sputum is mucous or muco purulent and contains greyish black particles mixed with a frothy fluid The dyspnœa is largely due to the accompanying emphysema and so indicates the degree of chron icity of the disease At first the patient may only notice that he gets out of breath on going upstairs or on mounting slopes, but later even walking on the level causes dyspnœa

Slight rises of temperature occur in the acute exacerbations of the catarrhal process Slight cyanosis is frequently observed especially after exercise when the accessory respiratory muscles are called into play Sometimes rhonchal fremitus is felt *Movement of the chest is restricted by emphysema, and the percussion note* then becomes hyper resonant On auscultation expiration is prolonged and sonorous or sibilant rhonchi are heard all over the lungs with bubbling râles if there is thin secretion in the smaller bronchi On the other hand, rhonchi may be scanty or only occasionally heard Voice conduction is unaffected The fingers may be lightly clubbed, and further evidence of venous obstruction may be apparent in the dilated venules on the cheeks or along the costal attachments of the diaphragm

Complications and Sequelæ —The following changes may occur in the lungs—peribronchial fibrosis bronchiectasis and emphysema Asthma or attacks of bronchial spasm sometimes form a complicating factor in chronic bronchitis especially in the cases of so called bronchorrhœa Emphysema may lead to pulmonary hypertension and right heart failure *Late in the disease as the result of the cyanosis* a peculiar form of confusional delirium is met with which is worse at night

Diagnosis —Chronic bronchitis must be distinguished from pulmonary tuber culosis bronchitis secondary to heart failure, and from bronchiectasis In tuber *culosis with bronchitis there is generally wasting and often flattening* of the chest wall owing to fibrosis of the lungs In all cases where the summer intermission of the symptoms fails suddenly rather than lessens gradually tuberculosis should be sus pected The diagnosis is clinched by the presence of tubercle bacilli in the sputum *In bronchitis secondary to heart failure in addition to the cardiac signs the râles* in the lungs are chiefly basal and the rhonchi are not so universally distributed In bronchiectasis the signs are usually characteristic and often limited to one lobe The radiograph will afford useful aid in diagnosis

Course —The disease once firmly established, unless relieved by suitable climatic treatment remains chronic and becomes progressively more severe as further damage is wrought in the lungs with each hibernal exacerbation As the emphysema develops a vicious circle is initiated the aerating power of the lungs diminishes and finally cardiac failure ensues

Prognosis —The immediate prognosis is good the ultimate is bad Much depends upon the patient s social condition and opportunities for treatment espec ially in respect to climate The expectation of life of a patient suffering from chronic bronchitis is considerably shortened

Treatment —Those subject to chronic bronchitis derive benefit from life in a warm equable climate In England the south western districts are best Well to do patients can sometimes prolong their useful life by wintering in warmer climates High altitudes should be avoided if emphysema is present or if there are cardiac complications Exposure to wet and chill is dangerous The question of occupation is often difficult Much time should be spent out of doors provided that the patient *is not exposed* to the inclemencies of the elements and further, the work under taken must not involve severe muscular efforts or the inhalation of dusty or irritant particles

In England it is difficult to find an outdoor occupation conforming with these

desiderata consequently light indoor work in a good atmosphere should be advised Clothing should be warm but light and afford special protection to the chest without overloading as some patients are liable to do Excesses in diet are to be avoided also alcohol and heavy smoking The general nutrition should be well maintained and many patients especially those of spare habit seem to derive great benefit from cod liver oil during the winter months

If cough is troublesome and expectoration tenacious or scanty various combinations of expectorant remedies are useful such as ammonium carbonate or chloride tinct ipecacuanhæ preparations of squills or senega with tolu liquorice or Virginian prune as flavouring agents A simple saline mixture such as R Sodii bicarb gr 10 sodii chlorid gr 3, sp chlorof min 5 aquam anethi dest ad fl oz 1 taken with an equal quantity of hot water in the morning or at night may help to clear the tubes and give the patient a spell of freedom from cough In older patients the ether and ammonia mixture may be given and in cases with bronchial spasm potassium iodide with anti spasmodics such as stramonium lobelia belladonna or grindelia may be of great value Various antiseptic drugs such as turpentine min 10 terebene min 5 to 10 creosote min 3 in capsules or perles have been recommended and the linctus thymi et diamorphin B P C min 60 Sedative lozenges such as compound liquorice heroin or codeine are often useful in checking useless cough Intercurrent attacks of acute bronchitis must be treated on the principles described under that condition and the patient kept indoors or in bed, as may be necessary When an advanced degree of emphysema coexists the treatment appropriate to that condition should be applied When failure of the right heart ensues the treatment must be modified suitably as described under emphysema Cultivation of the sputum and testing the organisms for sensitivity may indicate appropriate antibiotic treatment which can ameliorate the condition and suppress some of the infecting agents Breathing exercises often cause great improvement for both physical and psychological reasons

CHRONIC SUPPURATIVE BRONCHITIS

Synonym —Fetid Bronchitis

Ætiology —This condition is not sharply defined and is not a specific and separate nosological entity but it is a convenient group in which to include cases with fetid purulent sputum In some forms of chronic bronchitis the secretion may from time to time accumulate in the bronchi and prove offensive on expectoration In some instances this condition becomes chronic and the expectoration is fetid up to the time of death

Pathology —There is chronic inflammation of the bronchi with marked peri bronchial thickening The bronchial secretion becomes purulent and ulceration of the bronchial wall or dilatation of the lumen may occur Post mortem the lungs are soft and on section some broncho pneumonic areas with œdema of the bases may be seen Pus of an offensive nature exudes from the cut ends of the bronchi

Symptoms —These resemble those found in chronic bronchitis with in addition the unpleasant characteristics of the sputum in which Dittrich s plugs may be found These are small yellowish bodies with an intensely offensive odour composed of compact secretion

Complications and Sequelæ —Ulceration of the bronchial walls abscess or gangrene of the lung and areas of broncho pneumonia may develop As with bronchiectasis pyæmia sometimes ensues with the formation of secondary abscesses in the brain

Diagnosis —The sputum is offensive in abscess and gangrene of the lung bronchiectasis and interlobar empyema Radiographic examination of the chest is of great value in revealing these conditions and lipiodol investigation will usually serve to distinguish between them

Course —The disease is progressive but in the early stages there may be long remissions in which the sputum is not offensive although the bronchitis persists

Prognosis —As the disease becomes firmly established the patient s strength is gradually undermined from the absorption of toxins and death ensues in the course of a few years either from exhaustion toxæmia or pyæmia

Treatment —An endeavour should be made to diminish the degree of the infection and the quality of the sputum Cultivation of the sputum will show the organisms concerned and their sensitivity to various antibiotics will decide the appropriate treatment Postural drainage is usually helpful Apart from this treatment is as *for chronic bronchitis* The offensive odour can be partially altered or masked by creosote given by mouth or by inhalation

CHRONIC SECONDARY BRONCHITIS

Chronic bronchitis is a common association of chronic cardiac and renal disease Its clinical characters do not need special description It is only necessary to emphasise as in the acute forms, the *importance of recognising* that the bronchitis is not the essential condition, and that treatment must be directed especially to the primary disease

CHRONIC BRONCHITIS FROM MECHANICAL AND CHEMICAL AGENCIES

This usually proceeds to interstitial changes in the lung and these results may be studied more conveniently under the heading of the pneumoconioses

CHRONIC FIBRINOUS BRONCHITIS

Acute fibrinous bronchitis has been described above In certain cases of chronic catarrhal bronchitis a fibrinous exudate may occur from time to time with the formation of intrabronchial casts There is then cough and dyspnœa which abate with the expectoration of the cast It therefore very closely resembles acute fibrinous bronchitis and the treatment indicated is that described above

TUMOURS OF THE BRONCHI

Tumours arising in the bronchi may be (*a*) simple or (*b*) malignant

(*a*) *Simple tumours* —The following varieties occur Adenoma lipoma myxoma papilloma and chondroma Any of these may lead to bronchial obstruction and in consequence to *collapse* or *bronchiectasis* *Adenoma* is of sufficient frequency and importance to require separate description

(*b*) *Malignant tumours* —Primary carcinoma or sarcoma may originate in the bronchi Although the majority of primary malignant tumours within the lung originate in the bronchi either from the lining epithelium or from the cells of the mucous glands their pathological effects and clinical manifestations are in the main pulmonary and it is therefore more convenient to describe them as tumours in the lung (see p 1041)

ADENOMA OF BRONCHUS

Ætiology —Adenoma of the bronchus occurs about equally in the two sexes with a slight bias to the female sex and usually in adults below the age of 40

Pathology —The tumour is at first small and of polypoid form as a rule arising in a main bronchus but not infrequently in the branch to the lower lobe *It is about twice as common on the right side as on the left* The bulbous end *is generally directed towards the trachea* The surface is usually smooth and shiny but may be

nodular An erroneous diagnosis of carcinoma was not uncommon in the past owing to differences of staining of certain of the constituent cells and their irregular distribution in the connective tissues Metastases however are unknown An adenoma often projects through the bronchial wall giving it a dumb bell or cottage loaf conformation

Clinical Features —Often the earliest symptom is hæmoptysis and this may be slight or profuse since adenomata are very vascular and bleed easily In other cases the tumour causes bronchial obstruction with resultant cough and wheezing proceeding later to pulmonary collapse or bronchiectasis Dry pleurisy may be an early result of infection and at times pleural effusion or empyema may conceal the underlying cause

Diagnosis —Other causes of hæmoptysis must be considered such as pulmonary tuberculosis mitral stenosis dry bronchiectasis or bronchial carcinoma Pulmonary collapse may suggest an unresolved pneumonia In cases with pleural effusion or empyema the diagnosis is liable to be overlooked The injection of lipiodol or tomography will often reveal a blocked or deformed bronchus but the diagnosis can only be established by microscopical examination of a portion of the tumour removed through a bronchoscope

Prognosis —This varies with the stage at which the diagnosis is established If the condition is recognised early and treated before the growth has extended outwards through the bronchial wall and before bronchial obstruction and septic infection have occurred the outlook is favourable

Treatment —Lobectomy or if necessary pneumonectomy is now the treatment generally adopted especially if secondary bronchiectasis or fibrosis has developed Piecemeal removal through a bronchoscope is now seldom employed owing to the risks of hæmorrhage and of local recurrence

THE INFECTIVE GRANULOMATA

SYPHILIS —During the secondary stage a generalised hyperæmia of the bronchial mucous membrane may occur giving rise to slight bronchial catarrh with the usual symptoms and signs a condition that has been called syphilitic bronchitis It is frequently beneficially influenced by antisyphilitic treatment In the tertiary stage gummata may form in or near the large bronchi They tend rather to fibrosis and contraction than to softening and ulceration although the latter processes may occur Contraction may lead to bronchial stenosis with the symptoms and signs described below or to extensive peribronchial inflammation and bronchiectasis If the gummata extend into the lung as may happen in rare instances destructive lesions with cough expectoration and hæmorrhage may result This condition is more fully described in the section on pulmonary syphilis (see p 1040)

TUBERCULOSIS of the bronchi occurs as part of pulmonary tuberculosis and does not require separate description It may lead to bronchial stenosis pulmonary collapse and bronchiectasis

LEPROSY —The bronchi may be involved in this disease with the production of cellular infiltration and even nodule formation At first these lesions may produce bronchitis and they are progressive leading to cough expectoration wasting and asthenia The general clinical picture may simulate chronic pulmonary tuberculosis from which it is distinguished by the presence of leprous lesions elsewhere and the absence of tubercle bacilli from the sputum

BRONCHIAL STENOSIS AND OBSTRUCTION

Obstruction of the main bronchi or of their subdivisions within the lungs may arise from causes within the bronchi or from conditions outside them and these

Course—The disease is progressive but in the early stages there may be long remissions in which the sputum is not offensive although the bronchitis persists

Prognosis—As the disease becomes firmly established the patient's strength is gradually undermined from the absorption of toxins and death ensues in the course of a few years, either from exhaustion toxæmia or pyæmia

Treatment—An endeavour should be made to diminish the degree of the infection and the quality of the sputum Cultivation of the sputum will show the organisms concerned and their sensitivity to various antibiotics will decide the appropriate treatment Postural drainage is usually helpful Apart from this, treatment is as for chronic bronchitis The offensive odour can be partially altered or masked by creosote given by mouth or by inhalation

CHRONIC SECONDARY BRONCHITIS

Chronic bronchitis is a common association of chronic cardiac and renal disease Its clinical characters do not need special description It is only necessary to emphasise as in the acute forms the importance of recognising that the bronchitis is not the essential condition, and that treatment must be directed especially to the primary disease

CHRONIC BRONCHITIS FROM MECHANICAL AND CHEMICAL AGENCIES

This usually proceeds to interstitial changes in the lung and these results may be studied more conveniently under the heading of the pneumoconioses

CHRONIC FIBRINOUS BRONCHITIS

Acute fibrinous bronchitis has been described above In certain cases of chronic catarrhal bronchitis a fibrinous exudate may occur from time to time with the formation of intrabronchial casts There is then cough and dyspnœa which abate with the expectoration of the cast It therefore very closely resembles acute fibrinous bronchitis and the treatment indicated is that described above

TUMOURS OF THE BRONCHI

Tumours arising in the bronchi may be (*a*) simple or (*b*) malignant

(*a*) *Simple tumours*—The following varieties occur Adenoma lipoma myxoma papilloma and chondroma Any of these may lead to bronchial obstruction and in consequence to collapse or bronchiectasis Adenoma is of sufficient frequency and importance to require separate description

(*b*) *Malignant tumours*—Primary carcinoma or sarcoma may originate in the bronchi Although the majority of primary malignant tumours within the lung originate in the bronchi either from the lining epithelium or from the cells of the mucous glands their pathological effects and clinical manifestations are in the main pulmonary and it is therefore more convenient to describe them as tumours in the lung (see p 1041)

ADENOMA OF BRONCHUS

Ætiology—Adenoma of the bronchus occurs about equally in the two sexes with a slight bias to the female sex and usually in adults below the age of 40

Pathology—The tumour is at first small and of polypoid form as a rule, arising in a main bronchus but not infrequently in the branch to the lower lobe It is about twice as common on the right side as on the left The bulbous end is generally directed towards the trachea The surface is usually smooth and shiny but may be

In most cases pain discomfort and cough develop rapidly The cough may lead to the expulsion of the foreign body or may cause dyspnœa if it forces it up to the larynx The cough soon becomes noisy often paroxysmal and if local septic changes are set up expectoration occurs sometimes mucoid and copious at others muco purulent Hæmoptysis is not uncommon Pain may be absent but is often severe The temperature is generally normal for the first few hours but soon rises especially if bronchitis pneumonia or broncho pneumonia develop The further symptoms are those of the reactive changes and complications which ensue

The physical signs naturally depend upon the bronchus affected and upon the degree of obstruction They are at first those of deficient air entry The affected side may show less movement and there may be some recession of the lower inter costal spaces in young people If a large bronchus is involved and collapse results there is some displacement of the heart to the affected side Vocal fremitus may be diminished or absent the percussion note impaired and the breath sounds and voice sounds weak or absent over the whole or part of one lung almost invariably the lower lobe If the obstruction is valvular—*i e* allowing air to pass during inspiration and not during expiration—the lung behind the obstruction may become blown up and give the physical signs of localised emphysema The presence of an obstruction in a bronchus may cause a localised wheeze or rhoncus When bronchiectasis empyema or other conditions develop their characteristic signs become apparent

Complications and Sequelæ —These have been enumerated in describing the pathological results Sometimes septic meningitis or cerebral abscess develops

Diagnosis —The history of disappearance of some article from the mouth in the act of laughing breathing yawning coughing or sighing should always arouse suspicion of an inhaled foreign body If signs indicating bronchial obstruction are found the diagnosis is almost certain In every suspicious case radiographs of the chest should be taken in two different directions in case the shadow may be merged in that of the scapula or of the ribs The possibility of a foreign body should always be borne in mind in cases of unilateral basic bronchiectasis especially if no obvious cause can be found When such unilateral lung signs develop after an anæsthetic or after operations on the mouth or naso pharynx the possibility of some inhaled material should always be remembered

Course —Spontaneous relief may occur in two ways either by the foreign body being coughed up as may happen within a few hours or days or after an interval of months or years or the foreign body may track through the lungs and pleura and be discharged in an abscess bursting through the chest wall In both cases if an interval of more than days occurs irrecoverable damage may have resulted Apart from these occurrences and from successful treatment the course is very variable Death may occur quickly from some of the septic complications or after a longer or shorter interval from bronchiectasis gangrene or cerebral abscess

Prognosis —This is grave unless the foreign body is removed within 36 hours owing to the various dangerous complications that may ensue Excluding the few cases in which cure occurs by spontaneous discharge of the foreign body about 50 per cent of cases left untreated die within 1 or 2 years

Treatment —This consists in removal if practicable as soon as possible after the diagnosis is established If the foreign body is in a main bronchus or one of its principal divisions it can usually be removed by means of the bronchoscope and appropriate forceps In case of failure the question of pneumotomy may have to be considered If this is decided on every effort must be made to localise the foreign body by radiographic examination If intra pulmonary or pleural suppuration has occurred this must be dealt with surgically and sometimes the foreign body can be removed at the same time The medical treatment of the cases consists in that of the various conditions resulting

require separate consideration It is important to emphasise the fact that in both conditions the symptoms differ according to whether the obstruction is sudden and complete in which case collapse of the corresponding lung is the rule or whether it is partial and more gradual when bronchiectasis usually results Obstruction of the smaller bronchi may result from spasm as in asthma (see p 977) or from disease as in small tube and capillary bronchitis (see p 965)

(a) INTERNAL CAUSES

These are most conveniently considered in two groups—(1) Foreign bodies, (2) those due to disease or cicatrisation of the bronchial walls

(1) FOREIGN BODIES IN THE BRONCHI

These usually gain access through the larynx and trachea by inhalation Any inhaled foreign body that is small enough to pass down the trachea may reach a main bronchus, more commonly the right or if it is small it may pass into one of the secondary bronchi It may at once become impacted, or be moved by cough but unless it is expelled in this way it is sooner or later drawn into the smallest bronchus that will receive it and there becomes impacted

The recorded varieties of foreign body thus reaching the bronchi are very numerous but among the more common are pieces of bone beads pins coins ear rings studs, pencils fruit stones grains grasses beans nuts teeth and pieces of tonsil or adenoid growths after tonsillectomy Even a living fish has been inhaled into a bronchus Foreign bodies may reach the bronchi through a tracheotomy wound or a gland may ulcerate into the lumen of a bronchus Broncholiths and pneumoliths calcareous particles originating in the bronchi and lungs respectively may be inhaled *into a bronchus instead of being expectorated*

Pathology —The pathological changes resulting from a foreign body in a bronchus depend upon the nature of the foreign body the duration of its stay the size of the bronchus obstructed by it and the degree of obstruction induced If the foreign body is smooth and comparatively little septic and if it be removed within 24 hours or so complete recovery after a very mild local inflammatory reaction may be expected If on the other hand the foreign body is rough or soft and laden with septic organisms, acute pneumonic processes often septic in character may develop very rapidly A soft type of foreign body may swell and completely obstruct the bronchus it reaches leading to complete collapse of the corresponding lung area often the whole or half of the lower lobe If the stay of any foreign body is prolonged to days weeks months or longer irreparable damage almost invariably results The forms this may take are numerous Collapse and septic pneumonia have already been mentioned If the obstruction is partial septic bronchitis with stagnation of the bronchial exudate and pus behind the obstruction leads in turn to peribronchitis bronchiectasis and fibroid induration of the corresponding lung area In other cases gangrene of the lung results Not infrequently an empyema may occur and the foreign body may be found in the empyema cavity Suppuration round a foreign body may lead to localised intrapulmonary suppuration or abscess Simple bronchial obstruction uncomplicated by sepsis may lead to bronchiectasis owing to the resultant lowering of intrapleural pressure

Symptoms —During the passage of the foreign body through the larynx and trachea urgent symptoms may occur which leave no doubt as to what has happened but this is not invariable and the patient may not be sure whether he has inhaled or swallowed it In any case after a bronchus has been reached there may be a latent period which engenders a false sense of security and leads to delay in treatment

nant growth aneurysm of the aorta mediastinal abscess pericardial effusion and œsophageal new growths (2) *Intra pulmonary causes* generally primary or secondary new growths

Symptoms—These are practically identical with those just described but in addition there are those of the condition causing the pressure

Diagnosis—This has been discussed in the previous section The broncho scope should not be employed where there is any suspicion of an aneurysm

Prognosis—This is extremely unfavourable except in cases due to tuberculous glands and pericardial effusion and in some cases of mediastinal suppuration

Treatment—This can only be palliative in the majority of cases Useless cough may be checked by a sedative linctus of diamorphine (heroin) or morphine Dyspnœa when due to spasm may be lessened by inhalations of creosote and spirits of chloro form or by administration of oxygen Pain may be relieved by aspirin or other analgesic drugs Deep X ray therapy is of value in some of the malignant cases and should be tried in Hodgkin s disease or lymphosarcoma

ASTHMA

The term asthma has been loosely employed to denote any form of dyspnœa of expiratory type occurring in paroxysms For all conditions other than that now to be described some descriptive qualification should be employed to avoid confusion

Asthma or true spasmodic asthma is a paroxysmal affection occurring most frequently in patients of neuropathic inheritance It manifests itself in attacks of severe expiratory dyspnœa due to excessive vagal discharges set free by peripheral irritation chemical agencies or cerebral influences

Ætiology—Probably no other disease shows such a varied and complex causa tion but studies of idiosyncrasy and anaphylaxis have served to explain many of the obscurities

Predisposing causes—*Age*—The first attack may occur at any age even as early as the period of the first dentition The majority of cases begin before the age of 25

Sex—Asthma is generally stated to be nearly twice as frequent in the male sex as in the female

Heredity—Asthma certainly runs in families The heredity is not always direct the nervous instability sometimes being evidenced in other generations by migraine epilepsy or hysteria The view that hypersensitiveness to certain proteins is inherited is now discredited and it is believed that an unduly irritable bronchial centre is the factor transmitted by heredity

Other diseases—Bronchitis not infrequently leads to paroxysms in patients with asthmatic tendencies Tuberculosis of the lung occasionally induces it but here again it is probably in patients with the asthmatic diathesis

Climate and locality—Asthmatics seem very sensitive to both of these but no general relationship can be proved as the effects are most variable Some patients are better in dry others in damp foggy climates and in regard to locality each patient is a law to himself

Conditions of the nose and naso pharynx—Nasal obstruction from swelling of the turbinates deflection of the septum spurs and polypi and conditions of the naso pharynx such as adenoids and enlarged tonsils undoubtedly predispose to asthma and may also be exciting causes of the actual paroxysm

Exciting causes—Chemical substances—The emanations from certain animals may be the determining cause The best known of these are the horse and cat but rabbits hares guinea pigs deer dogs and monkeys may have a similar effect Even human hair appears capable of discharging the paroxysm The dust from some substances such as corn rice or oats the smell of certain drugs such as ipecacuanha,

(2) OBSTRUCTION OR STENOSIS FROM DISEASE OR CICATRISATION OF THE BRONCHIAL WALL

Ætiology —Primary bronchial new growths including adenoma columnar celled carcinoma oat celled tumour and squamous celled carcinoma lead to bronchial obstruction at an early stage These conditions produce symptoms and signs practically identical with those of new growths in the lung (see p 1041)

A plug of mucus or a blood clot may cause temporary obstruction of a large bronchus

The causes of cicatrisation are those leading to ulceration of the bronchial wall with subsequent healing such as syphilitic processes in and around the bronchi ulceration from injury produced by a foreign body or in its removal or by the inhalation of severe irritants Bronchial tuberculosis and the fibroid variety of pulmonary tuberculosis may also produce it

Pathology —The stenosis may occur in one of the main bronchi or in one passing to a lobe or to part of a lobe At first partial it may progress until the lumen is almost completely occluded at one point The changes occurring in the lung beyond the obstruction vary with its degree At first there is retention of secretion in the bronchi and air may be forced past the obstruction in inspiration but not expelled during expiration producing emphysema with gradual bronchial dilatation When the obstruction is more complete the air is absorbed the lung tissue gradually becomes fibrotic and the bronchi dilate further

Symptoms —Cough not infrequently of paroxysmal character is an early symptom and is usually a continuation of that caused by the primary condition It may be dry or associated with mucoid sputum sometimes blood streaked The expectoration may cause dyspnœa by obstructing the narrowed bronchus If bronchiectasis develops the sputum usually becomes fetid

The physical signs are those of collapse of a part of the lung and are progressive Local limitation of movement and flattening with displacement of the heart to the affected side may be apparent on inspection The vocal fremitus is diminished the percussion note impaired at first may progress to complete dullness when fibrosis develops The breath sounds are weak or even absent and the voice sounds diminished In the early stages a bronchial stridor may be audible Compensatory emphysema of the adjacent healthy lung tissue often develops

Complications —These are similar to those in stenosis from a foreign body, notably fibrosis and bronchiectasis

Diagnosis —Bronchial cicatrisation must be differentiated from obstruction due to extrabronchial causes such as pressure from new growths aneurysm and the other mediastinal conditions mentioned in the section below The history the physical signs and examination by radiography and if necessary by the bronchoscope may help in distinguishing The Wassermann reaction should be investigated in every case where the stenosis is proved to be of intrabronchial origin

Course —Unless the primary condition causing the stenosis is one which can be arrested by treatment the condition is progressive and eventually the area of lung beyond the obstruction becomes permanently functionless

Prognosis —This varies with the cause It is most favourable in cases due to syphilis submitted to treatment at an early stage

Treatment —Vigorous antisyphilitic treatment should be employed in cases due to syphilis In other cases the treatment is to relieve symptoms by appropriate measures Cases complicated by bronchiectasis are suitable for lobectomy

(b) EXTERNAL CAUSES

These may be subdivided into—(1) *Mediastinal conditions* chiefly enlargement of the bronchial or mediastinal glands from tuberculosis Hodgkin s disease or malig

include restlessness, irritability mental exaltation less frequently depression itching of the nose or chin flatulence or polyuria Some attacks are ushered in by coryza Such warnings are not constant and the sufferer usually wakes from sleep with a feeling of suffocation In early attacks great restlessness anxiety and alarm occur The difficulty in breathing and the sense of suffocation increase the patient sits up in bed or gets up to throw open the window and fixes his arms to bring into action all possible muscles of respiration Respiration although laboured and difficult is often slow inspiration being short while expiration is greatly prolonged Both are accompanied by loud wheezing sounds audible at a distance from the chest The patient appears pale but the lips are dusky and the expression is anxious and distressed The jugular veins are distended and prominent The accessory muscles of respiration are seen to be in violent action notably the sterno mastoids scalenes and pectorals The skin is moist and there may be marked sweating The chest is much distended and at each violent attempt at inspiration very little further enlargement occurs while there is often sucking in of the supra clavicular and lower costal regions

Percussion reveals marked hyper resonance and encroachment on the cardiac and hepatic dullness On auscultation inspiration is short and high pitched expiration very prolonged and both are obscured by abundant sonorous and sibilant rhonchi and later by bubbling râles at the bases The pulse is small quick and sometimes irregular There is usually marked epigastric pulsation A differential blood count during an attack may show an eosinophilia of as much as 35 per cent Cough does not develop until late in the paroxysm and is quickly followed in many cases by the expectoration of small pellets called perles by Laennec and often likened to boiled sago or tapioca These were carefully studied by Curschmann and when examined on glass on a black background prove to consist of a central highly refractive mucinoid coil with masses and threads of mucin wrapped spirally around it Microscopically leucocytes mostly eosinophils may be seen entangled in the mucus The sputum frequently contains Charcot Leyden crystals which are now accepted as spermin phosphate With the onset of expectoration the dyspnœa quickly lessens and the attack subsides The patient often passes a large quantity of pale urine and then may sleep until morning awaking in apparent comfort More frequently he appears pale tired and anxious

Diagnosis —*This involves the differentiation from other forms of dyspnœa* particularly those of spasmodic expiratory type The chief forms of paroxysmal expiratory dyspnœa are

1 *Bronchial asthma or spasmodic dyspnœa complicating chronic bronchitis and emphysema* —This condition is sometimes a late result of true asthma but may occur independently The dyspnœa is more persistent and is more definitely related to the bronchitic attacks being therefore more common in the winter

2 *Cardiac dyspnœa or cardiac asthma* —This like true asthma is usually nocturnal but the signs of failure of compensation in association with valvular or myocardial disease usually make the nature of the dyspnœa clear

3 *Uræmic dyspnœa or renal asthma* —This is also not infrequently nocturnal and may be almost indistinguishable from true asthma Examination of the urine the urea and non protein nitrogen content of the blood usually enable the distinction to be made with certainty Cardio vascular changes with high blood pressure are frequently but not invariably present

4 *Hay asthma* is probably only a severe form of hay fever and is to be regarded as a variety of true asthma

5 *Pulmonary tuberculosis may be associated with asthmatic dyspnœa* —The differentiation may not be easy during the attack but the persistence of apical signs in the interval may give a clue It is a wise precaution *to X ray the chest of all patients* with asthma when first seen and at intervals if there are suspicious symptoms

The dyspnœa of laryngeal or tracheal obstruction and of mediastinal pressure can

and the scent and the pollen of grasses and flowers may act in a similar fashion as also may articles of diet and many drugs It is claimed that at least 50 per cent of asthmatics show hypersensitiveness to various protein antigens obtainable from animals, grains, bacterial bodies foods and drugs and over a hundred are now available for routine testing of these patients The analogy with the causation of hay fever and paroxysmal sneezing is obvious This group has been referred to as "allergic asthma

Peripheral irritation —As already mentioned irritation of the nose naso pharynx and bronchi may be asthmogenic in those of asthmatic tendency

Gastro intestinal disturbance —This is well recognised as a cause and most asthmatics find by experience the penalties of a heavy late meal and of indigestible articles of diet It is possible that actual metabolic errors may be a factor as in the so called 'week end asthma', due to altered conditions of diet and exercise at this period

Ovarian disturbance —Asthma may occur fairly regularly about 10 days before the onset of each period This is probably due to lack of progesterone from a primary ovarian defect or from an insufficient production of the gonado tropic luteinising hormone produced in the pituitary Satisfactory results are usually obtained by the injection of a preparation such as Synergon 1 ml containing 10 mg of progesterone and 1 mg of œstrone per ml This may be injected every other day during the 8 days before the period is due

Cutaneous —Asthmatics are peculiarly liable to urticaria and eczema, although these conditions usually alternate with the asthmatic attacks

Nervous factors —Fatigue emotion and nervous shock may precipitate an attack This factor cannot be ignored even in cases due to protein hypersensitiveness as is shown by a well known case in which a patient susceptible to roses developed asthma when handed an artificial rose

Pathology —Numerous theories have been propounded to explain the asthmatic paroxysm Among these may be mentioned vascular turgescence of the bronchial mucous membrane spasm of the bronchial muscle and increased secretion of the mucous glands Spasm of the diaphragm or of the inspiratory muscles has also been suggested That bronchial spasm plays the major part seems to have been established by the experiments of Brodie and Dixon and this view is strongly supported by their observations on the effects of drugs on the bronchial musculature Muscarine pilocarpine and physostigmine produce bronchial constriction and asthmatic symptoms in animals while atropine hyoscyamine and chloroform abolish these effects

There can now be little doubt that the broncho constrictor fibres of the vagus are the channel by which the impulses discharging the asthmatic paroxysm reach the bronchi although the possibility that impulses leading to vaso dilatation and to increased bronchial secretion are also concerned must be admitted

Anaphylaxis —The important part played by extraneous proteins in the genesis of asthma and the obvious analogy between the asthmatic paroxysm and the symptoms of anaphylactic shock have suggested that in many cases if not in all asthma is an anaphylactic phenomenon Evidence is accumulating in support of this view It has been shown that the lungs of the guinea pig killed in anaphylactic shock show extreme constriction of the bronchioles Asthmatics are well known to show anaphylactic tendencies and especial care in the administration of antitoxic serums is necessary with them It is of some interest to note that the Eppinger and Hess group of vagotonics show urticaria dermatographia eosinophilia and liability to anaphylactic shock all conditions which occur in asthmatics It is tempting therefore to assume that the foreign protein or toxin produces the asthmatic attack by inducing vagotonicity Further research is needed before it can be accepted that anaphylaxis accounts for all cases of asthma but it is almost certainly an important factor in many

Symptoms —The asthmatic paroxysm most commonly commences about 2 a m or later but it may sometimes develop in the daytime There are often preliminary indications some hours beforehand constituting the asthmatic aura These

Cortisone and corticotrophin are sometimes said to be most efficacious The value of these substances in this condition is not fully established but they should be tried if relief is not given by other remedies The recommended dose of cortisone by mouth is 300 mg on the first day, 200 mg on the second day, 100 mg on the third day and thereafter 75 mg daily

Many expectorant and anti spasmodic drugs have been used in treatment, potassium iodide and bicarbonate with tincture of stramonium hyoscyamus or lobelia is sometimes found comforting Suitable sedatives are paraldehyde phenobarbitone or sodium amytal in moderate doses Morphine should never be given to an asthmatic at any stage In an early stage it will cause addiction in an advanced stage it may and often does cause death

(*b*) *Between the attacks*—General advice—Asthmatics should be taught to live as normal a life as is possible under the circumstances There is usually no reason to restrict either their activities or diet although patients who have nocturnal attacks find that heavy meals at night precipitate attacks and they may therefore find it advisable to have their main meal in the middle of the day Attempts to find health by changing houses and occupation are not usually successful in themselves Migrants *from the towns in search of health are crossed by migrants from the country* with similar intentions and the benefits derived from the change seem to be equally divided between the two groups

It has been observed that some patients are sensitive to contact with certain allergens mostly of a protein nature such as pollen animal and vegetable hair house dusts and similar substances From this observation has risen the suggestion that nearly all cases are attributable to one or more sensitisations of this nature that these sensitisations can often be detected by performing skin tests with a wide range of protein substances and that desensitisation can be carried out by injecting small doses of the sensitising agents and by increasing the dose until desensitisation is achieved The theory of this treatment is an attractive one and a vast literature has grown up on the subject

Similar importance has been given to treatment with autogenous vaccines prepared from the sputum or with stock vaccines It is doubtful whether either of these two methods of treatment have anything more than a psychological value and while apparent improvement frequently takes place during such treatment it is more often due to the psychological effect of an impressive treatment and the personality of the doctor than to any desensitising effect

Attempts are made to treat patients by special diets Children are the especial victims of this form of therapy There is little evidence that bronchial asthma is ever caused by the ingestion of any particular food substance although such ingestion occasionally causes alimentary symptoms The effect of these diets is often to make patients even more introspective than they naturally tend to be

Exaggerated attempts are sometimes made to render allergen free the atmosphere in which the patient lives or sleeps Such measures condemn the patient to discomfort and disappointment The fact that many sufferers from asthma also suffer from rhinorrhœa have nasal polyps deflected septa or sinus infection has led to many misguided surgical and electrical misadventures All these treatments and many others had and have their strong adherents amongst doctors and even patients

There is an especial difficulty in assessing the value of any special treatment in asthma since the natural history of the disease is so variable and sufferers from it are so susceptible to suggestion In default of any specific treatment there are general measures and advice which are helpful The patient should be advised to try and not let his asthma dominate his life Children should go to normal schools and play games as normally as possible There is no need for a special diet except that patients are usually well advised not to have a heavy meal in the evening as a full stomach when recumbent appears to cause attacks They should avoid dusty house cleaning

usually be recognised by the fact that it is chiefly of inspiratory type and may be associated with stridor instead of wheezing In all cases of doubt the chest should be examined radiographically to exclude aneurysm retrosternal goitre or new growth

Course, Complications and Sequelæ—Such an attack may last from a few minutes to several hours and may remit and then return When the spasm is very severe and prolonged into hours with little or no remission, the condition is often termed status asthmaticus The patient may be extremely ill and death may occur unless the attack remits spontaneously or as a result of treatment More often the attacks recur at the same time each night for a considerable period extending to weeks, and then pass off, after which the patient may enjoy a period of freedom of weeks or months The intermissions may become shorter with successive attacks and increasing emphysema may develop This in turn leads to secondary bronchitis which persists together with some degree of permanent œdema of the bases Later still the cardio vascular changes incidental to emphysema occur as sequels, namely engorgement of the right heart tricuspid regurgitation venous stasis ascites and œdema Chronic asthmatics frequently present a characteristic appearance Of thin build, with sallow complexion anxious expression and nervous manner, they often have a long neck, high straight shoulders and a forward stoop Asthma necessarily imposes limitations upon those who suffer from it at all severely although many asthmatics lead active useful lives in spite of their disease

Prognosis —*When the disease starts in childhood or in early adult life it may* stop spontaneously or be relieved permanently when some causal condition is dis covered and treated During a severe attack the aspect of the patient may be so alarming that a fatal issue may seem imminent yet death rarely occurs In chronic cases the ultimate prognosis is made more serious by the complicating emphysema and bronchitis and in spite of popular belief the asthmatic has less than the normal expectation of life

Treatment—(*a*) *During the attack*—The list of anti spasmodic drugs and meas ures employed is a long one and it is impossible to foretell which will be efficacious for asthmatics vary as widely in their response to drugs as they do in regard to asthmo genic causes Drugs may be administered for this purpose by inhalation by nasal sprays by the mouth or by hypodermic injection Adrenaline hydrochloride in doses of 2 to 5 minims of a 1 in 1000 solution hypodermically may act with dramatic efficacy if administered sufficiently early, but it should be given cautiously to elderly asthmatics It may also be combined with pituitary extract as in the special prepara tions Evatmine Pitrenalin and Kadamysin In status asthmaticus the procedure suggested by Hurst may give relief A syringe of 1 ml capacity is filled with adrenaline solution 1 in 1000 This is slowly injected over a period of several minutes to half an hour or until the spasm relaxes When relief has been obtained a preparation with a more prolonged action may be used such as adrenaline mucate (hyperduric adrenalin) or adrenaline combined with chlorbutol and glycerin (adrenutol) An intramuscular injection of 0 5–1 0 ml of one of these will help to prevent a recurrence for 6–8 hours Ephedrine hydrochloride in tablets of gr $\frac{1}{2}$ to $\frac{3}{4}$ has proved itself a useful substitute for adrenaline in some cases and can be given by the mouth Pseudo ephedrine in doses of gr $\frac{1}{2}$ to 1 is often helpful where ephedrine fails Adrenaline often proves helpful as a nasal spray especially in combination with Chloretone Intravenous injections of 50 or 100 mg of nicotinic acid may give relief when adrenaline fails An oxygen tent is sometimes of great value in the treatment of status asthmaticus Intravenous aminophylline in doses of 0 25 g in 10 ml of distilled water is often effec tive especially when intramuscular adrenaline has failed It may also be given in doses of 0 5 g per rectum

It is often advisable to move cases in status asthmaticus to hospital or nursing home The change of surroundings and the different psychological atmosphere often relieves the condition

considered (1) The most important is the localised collapse which leads to secondary bronchial dilatation (2) Weakening of the bronchial walls Most of the conditions preceding bronchiectasis tend to induce severe bronchitis and peribronchitis and thus render the walls more yielding Where stagnation of secretion occurs septic and putrefactive organisms develop producing tryptic ferments which may act injuriously upon the lining membrane (3) Increased pressure on the walls thus weakened is the determining factor This is generally expiratory in origin and due to the strain of cough The actual pressure of secretion accumulating behind an obstruction may promote yielding of the bronchial walls In cases of bronchiectasis following on collapse of the lung the force of inspiration has been regarded as contributory but this is doubtful and in any case is less important than the expiratory strain of cough (4) The fourth possibility is the traction exerted upon the walls of the bronchi by contracting connective tissue in the surrounding fibroid lung This obviously postulates the existence of pleural adhesion which is not invariably present While this must be admitted as a possible contributory factor its importance is certainly less than that of the preceding ones

Congenital bronchiectasis is a pathological rarity and may be confused with congenital cystic disease of the lung (see p 1044) It is usually unilateral and the bronchi involved are of small size although in some cases the lung may show a large central cavity with smaller spaces around it Bronchiolectasis is also more of pathological than of clinical interest It occurs chiefly in children as the result of acute broncho pneumonic processes It is said sometimes to follow influenza and possibly tuberculosis The lung has a peculiar spongy appearance to which the name honey comb has been applied

Bronchiectasis of the larger tubes may be either cylindrical or saccular In the former condition several of the bronchi are more or les uniformly dilated and when opened out they appear like the fingers of a glove Sometimes the dilatations are fusiform at others they show a beaded arrangement described as moniliform These forms of dilatation are usually associated with emphysema and chronic bronchitis Saccular bronchiectasis is generally localised and may be found in any part of the lung but is most common in the lower lobes and near the base This is partly due to the fact that the antecedent processes fall with special stress on the bases of the lung and partly to the influence of gravity in leading to retention of secretions in these parts Although it may be unilateral in origin it often spreads and may involve both bases or even all the lobes There may be one large irregular cavity or a series of smaller globular dilatations involving the whole or part of the walls of one or more bronchi The cavities are usually filled with the fetid secretion to be described under expectoration When this is washed away the walls are found to be thin smooth and formed of thinned out mucous membrane In places this may have ulcerated owing to the tryptic action of the secretion and the lung tissue is thus exposed An abscess may then form and an aneurysm sometimes develops as in a tuberculous cavity The openings of the smaller bronchi derived from the dilated bronchus can often be recognised in its walls In doubtful cases the histological demonstration of cartilage and muscle in the walls establishes the bronchial origin of a cavity The surrounding lung tissue is usually airless and fibroid and sometimes is almost of leathery consistence Occasionally however it is emphysematous congested or pneumonic In the great majority of cases there is a dense pleural adhesion over the area of lung involved

Other morbid conditions found post mortem include lardaceous disease gangrene of the lung empyema pyo pneumothorax suppurative pericarditis and cerebral or spinal cord abscess Owing to the obstruction of the pulmonary circulation which may result engorgement and dilatation of the right side of the heart, tricuspid regurgitation and the results of systemic venous stasis are often found

Symptoms —The onset is usually insidious the symptoms developing during

and keep out of dusty atmospheres If they are sensitive to horse dandruff vegetable pollens or other single substances they should avoid them and the patients usually recognise these substances without having to have skin tests to identify them They should receive instruction in the use of ephedrine or if this is ineffective or loses its effect adrenaline by injection or by inhalation Knowledge that one has the means of relief at the outset of an attack often means that the attack will not develop Many of the proprietary inhalants and patent inhalers are quite effective if used early enough Most patients benefit from instruction in expiratory breathing exercises which may of course act by suggestion but which also have a manifest effect on the mobility of the chest and the respiratory excursion

Advice to change a patient s home or occupation should not be given lightly Such steps are rarely effective unless there is some very real and obvious domestic or occupational hazard

Cortisone and corticotrophin are not usually required in the treatment of chronic asthma but they have been used with great benefit at times when all other measures have failed Cortisone may be administered orally in such cases in the form of cortisone acetate tablets An initial dose of 200 mg followed by 100 mg daily for 2 or 3 days may be necessary at the commencement of treatment Thereafter symptoms can usually be controlled by quite small doses 25 mg to 50 mg at bedtime usually being sufficient

BRONCHIECTASIS

Definition —Bronchiectasis is a condition of permanent dilatation of one or more bronchi When it occurs in the finer divisions it is sometimes described as bronchiolectasis

Ætiology —Bronchiectasis is invariably secondary and may result from disease of the bronchi, the lung parenchyma or the pleura Even the rare congenital cases are probably consequent on malformation atelectasis or intra uterine disease

1 The bronchial conditions which may progress to dilatation are bronchitis, and any affection leading to partial bronchial obstruction such as plugs of mucus an inhaled foreign body a tumour (simple or malignant) stenosis from cicatrisation and external pressure from new growth or aneurysm, or enlarged bronchial glands from any cause but more especially from tuberculosis Localised pulmonary collapse thus induced seems to be the commonest antecedent condition In children measles and whooping cough are not uncommon causes especially when they follow one another in rapid succession although either alone if severe, may lead to it

2 Conditions of the lung parenchyma which may cause bronchiectasis are un resolved pneumonia broncho pneumonia collapse syphilis and tuberculosis Syphilis is rare and usually acts by leading to bronchial obstruction or stenosis Fibroid tuberculosis is a common cause but the clinical manifestations are as a rule masked by the primary condition The pulmonary complications of influenza are not in frequently followed by bronchiectasis A diffuse type of bronchiectasis is sometimes found in long standing cases of asthma

3 The pleural conditions which are followed by bronchiectasis are those which lead to pleural adhesion and those which are associated with pulmonary fibrosis notably chronic pleural thickening or empyema leading to prolonged or permanent collapse of the lung

In a lesion with such diverse antecedents the age relations are necessarily indefinite It may occur at any age but is commonest in the third and fourth decades It fre quently commences in childhood although the characteristic clinical manifestations may not develop until adult life

Sex —In most recorded statistics there is a striking preponderance in the male

Pathology —Four factors in the pathogenesis of bronchial dilatation have to be

pericarditis may develop and prove fatal Septicæmia and pyæmia sometimes occur as terminal results Cerebral abscess constitutes a serious and somewhat common complication in heavily infected cases and may be found in the frontal parietal or temporal regions or suppuration may occur in the cerebellum or cord Occasionally multiple abscesses form Lardaceous disease sometimes develops especially in the liver kidneys and intestines Multiple infective arthritis is an occasional complication

Diagnosis—In well developed basic cases this is as a rule easy The history of cough influenced by posture and associated with copious sputum is suggestive especially when variable physical signs are observed The development of the characteristic sputum with these signs renders the diagnosis almost certain and the radiograph usually serves to confirm Radiological investigation after an intra tracheal injection of 10 to 20 ml of lipiodol through the crico thyroid membrane or between two rings of the trachea under local anæsthesia or with care directly between the vocal cords has greatly facilitated the diagnosis of bronchiectasis Franklin has recommended the nasal route for the introduction of the lipiodol One nostril the oro pharynx and the larynx are anæsthetised then a gum elastic catheter is passed along the floor of the nose into the larynx Procaine or other local anæsthetic is injected down the catheter and the lipiodol follows Tilting and turning the patient in appropriate directions is done in order that the lipiodol should pass into the diseased portions of the bronchial tree The injection should be carried out in the radiographic room and the patient instructed to restrain cough if possible until the films have been taken The pictures obtained are strikingly characteristic and of great value In cases with less characteristic symptoms and signs the distinction has to be made from chronic bronchitis especially the fetid variety pulmonary tuberculosis gangrene or abscess of the lung and fetid empyema The distinction from chronic bronchitis may be difficult especially in the early stages when the sputum is not fetid but the paroxysmal cough the copious expectoration with signs including bronchial breathing and sticky râles at the base may be strongly suggestive In fetid bronchitis the fetid sputum is not constant and the cough and sputum may occur only during exacerbations of the bronchitis Pulmonary tuberculosis may give rise to difficulty particularly in cases of apical bronchiectasis Repeated examinations for tubercle bacilli and also for elastic tissue in the sputum should be made The history the mode of spread and radiographic examination may all assist It should be remembered that the two conditions may coexist and this may be suspected in some cases of fibroid tuberculosis with basic excavation Abscess and gangrene of the lung have a more acute onset and course but the chronic cavities left by these conditions may give rise to difficulty In such cases the history may be an important aid in diagnosis In fetid empyema rupturing through the lung particularly when of interlobar origin the patient is generally acutely ill there may be a history of pleurisy at the onset and possibly some evidence of mediastinal pressure or cardiac displacement The rare condition of congenital cystic disease of the lung may give rise to some difficulty (see p 1044)

Course—This depends on the extent of the bronchial involvement and the degree of infection Probably only a small percentage of cases of bronchiectasis are clinically diagnosed Those that are are usually both extensive and heavily infected Without treatment the condition tends to be progressive and leads to complications many of which are lethal

Prognosis—Surgeons and physicians tend to have different ideas about the prognosis of bronchiectasis the former are often of the opinion that without surgical treatment the prognosis is hopeless and the expectation of life short The latter are not quite so pessimistic The reason for this difference of opinion is that the surgeon tends to see a rather special selection of the worst cases the physicians see these and also many cases which are little or at all progressive

the course or as a sequel of one of the acute or chronic affections mentioned above In some few cases however they develop rapidly in patients previously in good health This is particularly the case where bronchiectasis results from an inhaled foreign body or after general anæsthesia and a rapid onset should lead to the suspicion of this The cough in well developed cases is somewhat characteristic and occurs in paroxysms These are frequently induced by change of posture—for example bending forward or lying down They occur with *special frequency on rising* and are usually associated with the expectoration of large quantities of sputum due to the *overflow of the secretion accumulated in the cavities during the night*, into a sensitive or relatively healthy bronchus, which excites cough reflexly They also occur on retiring to bed and at long intervals during the day The sputum frequently amounts to as much as 20 or 30 oz in the 24 hours It is generally extremely fetid although in the earlier stages this is not invariable The patient s breath is often also malodorous and the stench may pervade the room or even the house in which he lives although it is not persistent The patient is himself much distressed by the unpleasant character of the sputum of which he is as a rule, acutely conscious On standing in a glass vessel it can be seen to settle into three layers—a surface scum of light frothy mucus an intermediate stratum of thin turbid greenish fluid and a deep layer of brownish colour consisting of muco pus bacteria anaerobes spirochætes and *putrefactive products including foul smelling organic acids Fetid yellow bodies* called Dittrich s plugs can usually be found in the deep layer Elastic tissue is only present when erosion of the wall has occurred Hæmoptysis is not infrequent and may occasionally be fatal It may be the first and only symptom in some cases which are referred to as dry or silent bronchiectasis ✓ Dyspnœa is not as a rule apparent unless the condition is widespread or unless the pulmonary or cardiac complications are present The general condition of the patient is at first but little affected and there may be no fever for long periods As the disease progresses lassitude anorexia and some wasting slowly develop while bouts of fever occur due to retained secretions or to some complication

Physical signs vary with the extent and degree of dilatation and also with the *amount of secretion present In the early stages there is at most slight dullness at* one base with diminished air entry peculiar sticky leathery rales and diminished *vocal resonance When bronchiectasis is well developed the signs are* almost characteristic The patient may appear well nourished and of good colour although on cold days *especially in children duskiness or cyanosis is often noticeable* There is well marked clubbing of the fingers generally of drum stick character and pulmonary osteo arthropathy involving many joints sometimes *develops There may* be localised *flattening or retraction* of the chest wall over the affected area with diminished movement and the heart is drawn over to this side The *remaining signs* vary with the state of the cavity If this is full there is diminished vocal fremitus dullness and weak or absent breath sounds and voice sounds If the cavity is *empty* or partly empty the vocal fremitus is increased the percussion note is boxy or dull while the breath sounds are bronchial or cavernous Adventitious sounds are *then* generally audible the most characteristic being sharp metallic or leathery râles Bronchophony and pectoriloquy are marked and occasionally the veiled puff of Skoda can be heard Signs of bronchitis are often apparent in the adjacent lung tissues compensatory emphysema may be demonstrable in the unaffected parts of the lung *and on the opposite side* Radiographic examination before and after the injection of lipiodol serves to define the extent of the disease and the degree of fibrosis Tomography *may also be useful*

Complications and Sequelæ—The chief pulmonary complications are septic *broncho pneumonia gangrene and abscess* The pleura may become involved giving rise to dry pleurisy which sometimes progresses to empyema and rarely to pyo pneumothorax *while in other cases pleural* adhesion and contraction result Septic

DISEASES OF THE LUNGS

HYPERÆMIA AND ŒDEMA

Hyperæmia of the lungs may be either active or passive In the former there is an increased supply of arterial blood through the pulmonary and bronchial arterioles In passive hyperæmia there is engorgement of the pulmonary venous radicles and capillaries With both forms there is frequently œdema due to the exudation of serous fluid into the lung alveoli The term congestion' is sometimes employed as an alternative to hyperæmia but owing to its erroneous popular use it is best avoided

(a) ACTIVE HYPERÆMIA

Ætiology—This may occur in association with any acute inflammatory process affecting the bronchi lungs or pleura It sometimes results from the inhalation of pulmonary or bronchial irritants such as poisonous gases or heated air Severe muscular exertion and exposure to extreme cold are described as causes but the former at least is doubtful An important variety is that known as *collateral or flux ionary hyperæmia* which occurs when there is obstruction to the circulation in the whole or part of one lung from conditions such as a large or rapidly developing pleural effusion an extensive and spreading pneumonia or in association with pneumo thorax This may develop in the sound lung or in the unaffected parts of that diseased A primary form of acute hyperæmia the maladie de Woillez has been recognised by French authors but this is generally regarded as a mild or abortive pneumonia

The clinical manifestations of acute hyperæmia are merged in those of the pro cesses with which it is associated and therefore do not need separate description

(b) PASSIVE HYPERÆMIA

Ætiology—Passive hyperæmia may be produced by conditions impeding the venous return from the lungs The commonest causes of impeded return are left sided heart lesions causing overfilling of and increased pressure in the left auricle In mitral stenosis it may occur early and sometimes almost acutely but aortic and myocardial lesions also lead to it when the left ventricle fails and the mitral valve yields Direct obstruction of the pulmonary veins sometimes results from external pressure by aneurysm mediastinal tumour or enlarged bronchial glands or from obstruction of the lumen by thrombosis

Passive hyperæmia is obviously in the main dependent on mechanical factors it is not surprising therefore that gravity seems to play a part in the localisation of its effects which are usually most marked in the bases or most dependent parts of the lungs In bedridden enfeebled or old patients particularly if myocardial weak ness or degeneration coexists this factor becomes of great importance Not in frequently some degree of œdema of the bases develops and the condition is then called hypostatic congestion If such an area becomes infected the resulting process is known as hypostatic [illegible] al hyperæmia and œdema of the hypostatic type also result [illegible] ses such as enteric fever from poisoning by [illegible] al event in many cerebral lesions causing

[illegible] pillaries are engorged with the result [illegible] le the alveolar walls and septa are [illegible] ent derived from the hæmo [illegible] ited in the epithelium of the

Given morbid anatomical bronchiectasis the prognosis is uncertain but severely infected cases with much foul sputum repeated hæmoptyses and pyrexial episodes are progressive with a short expectation of life failing adequate treatment, but there are exceptions even to this

Treatment —The medical treatment of bronchiectasis consists of efforts to secure efficient emptying and drainage of the affected part of the lung to lessen or control the infective processes occurring in the lung and to promote the general health and well being of the patient Bronchograms of the affected lobe or lobes indicate the desirable position for evacuation of the lung In bronchiectasis of the lower lobes the patient either bends over or his feet are raised so that the bifurcation of the trachea is below the level of the affected lung If the anterior bronchi are affected he lies on his back and if the posterior bronchi are affected he lies on his face He should also be tilted on his side so that the affected side is uppermost The best position for drainage can usually be found by a process of trial and error The longer the appropriate position is maintained the more effective the result In any case it should be maintained for not less than 30 minutes at a time The initial instruction is best given by a qualified masseuse and the treatment must be maintained for life if the lobe is not going to be removed surgically The Nelson bed hinged in the middle is helpful in maintaining the correct posture long enough for drainage to occur

The sputum should be cultivated and the organisms identified and their drug sensitivity tested The quantity and degree of infection can be altered by the appropriate use of antibiotic preparations although the development of drug resistance reduces their effectiveness They are especially valuable during pyrexial periods of exacerbation of infection due to defective drainage Penicillin inhalations have some limited effect but no drug is really effective if the drainage from the affected bronchi is poor

Creosote given by inhalation or in capsule of 3 minims was much used in the past and it has value in helping to disguise the fœtor of the breath which is one of the most distressing features of these cases Bronchoscopic aspirations have been found effective in some cases especially those where bronchostenosis or bronchial œdema prevents effective drainage

The possibility of treatment by surgical segmental resection by lobectomy or pneumonectomy should be considered Surgeons have no doubt about the value of prophylactic surgery and may advise resection for anatomical bronchiectasis without symptoms Many physicians are not so convinced of the necessity of these resections Differences of opinion represent a different idea of the prognosis There is unanimity about the desirability of resection for the infected cases with much sputum daily with repeated pulmonary hæmorrhages or with a history of recurrent attacks of pneumonia or pyrexial episodes Thoracic surgery has had no more dramatic successes than in these cases Unfortunately in many of the worst cases the disease is too extensive for removal to be possible In these cases medical treatment palliates and prolongs life

INJURY

External trauma applied to the chest wall may cause rupture of a main bronchus This is especially liable to occur after severe crushing accidents One or other of the main bronchi may be completely severed from the trachea The chief clinical feature presented in such a case is emphysema of the neck and upper portion of the chest wall Death usually ensues in 2 to 3 days

R A YOUNG
G L BEAUMONT
F R BOLAND

of greyish yellow or pinkish fluid Frothy fluid of similar character is found in the bronchi and even in the trachea and naso pharynx in hyperacute cases

Symptoms—The onset is sudden and generally occurs when the patient is lying down hence being most frequently observed at night The patient awakes with intense dyspnœa and a sense of suffocation then frequently rolls or rushes about in the endeavour to breathe even clutching at the throat Cyanosis is present and the aspect is one of anxiety and alarm Frothy fluid often pink in colour may soon stream from mouth and nose or be brought up in great gulps The chest movements are hurried and the accessory respiratory muscles are in violent action Vocal fremitus is diminished over the lower lobes The percussion note soon becomes impaired over the lungs commencing at the bases The breath sounds are at first vesicular or harsh with prolonged expiration then become faint and may be obscured by bubbling râles or crepitations audible all over the chest Voice conduction is diminished

Complications and Sequelæ—Owing to its acute and rapid course complications do not occur Bronchitis may result as a sequela

Diagnosis—The affection is usually so characteristic that the diagnosis is obvious In the more protracted cases the dyspnœa and the physical signs are not unlike those of acute suppurative bronchitis or suffocative catarrh and broncho pneumonia but in both of these there is some degree of fever and the expectoration is less copious and when it occurs is usually of purulent or muco purulent character The nocturnal onset of œdema may suggest asthma but the physical signs and the late and scanty expectoration in the latter suffice to distinguish it

Course—The malady usually lasts only minutes or hours Unless it remits or treatment affords relief the patient rapidly becomes unconscious and death follows the heart continuing to beat after respirations have ceased

Prognosis—The prognosis is always very grave but prompt treatment has saved some cases Death may occur in less than 10 minutes or be delayed for 24 or 48 hours

Treatment—The most successful treatment is the immediate subcutaneous injection of morphine gr $\frac{1}{4}$ Good results have also followed the injection of atropine sulphate gr $\frac{1}{100}$ to $\frac{1}{60}$ hypodermically Intravenous injection of aminophylline has been recommended The dose is 0 25 g in 10 ml of distilled water Oxygen inhalation by nasal catheter or the B L B mask or oxygen tent is of value in some cases others derive no benefit from it Prompt venesection has been recommended

(*d*) CHRONIC PULMONARY ŒDEMA

This is usually the sequel of chronic passive hyperæmia and the causes and symptoms are those of that condition It may also occur in chronic renal disease In marked degrees of œdema however the signs may closely simulate those of pleural effusion save for the displacement of the cardiac impulse It is important to remember that some degree of hydrothorax may occur as a complication and increase the difficulty in diagnosis

INFARCTION OF THE LUNGS

Infarction of the lungs or pulmonary apoplexy results when a branch of the pulmonary artery becomes occluded by embolism or thrombosis

Ætiology—*Embolic forms*—The obstructing plug may originate in any part of the systemic venous system in the right side of the heart or on its valves or in the pulmonary artery itself The commonest peripheral cause of embolism is detachment of a thrombus in cases of thrombo phlebitis This may occur in the veins of

alveoli and in the fibroblasts in the inter alveolar septa In long standing cases the lung is firmer than normal and brownish red in colour a condition described as *brown induration* If any degree of œdema is present serous fluid is found in the alveoli on post mortem examination and on section of the lung frothy serous fluid exudes which may contain some of the pigmented alveolar cells constituting what are called ' cardiac cells ' Although congested and œdematous lung is heavier than normal, it usually floats in water

Symptoms —In slight degrees of hyperæmia these may be absent or negligible In more advanced cases they are those resulting from the impeded circulation through the lungs and the deficient aeration which this entails Dyspnœa is the most prominent symptom and it is generally a measure of the degree of hyperæmia It is markedly increased by exertion of any kind and in extreme degrees it is distressing and eventually alarming It may be inspiratory or expiratory in type, and in the latter case it is sometimes described as cardiac asthma In severe cases there is usually orthopnœa Cough is almost invariably present, and there is usually some expectoration of frothy fluid, which may be blood stained The pigmented cells referred to above as cardiac cells may be found in it Cyanosis is common and indicates the degree of anoxæmia This may be associated with distension of the jugular veins and there is often obvious distress As in other forms of cyanosis there is usually some increase in the number of red corpuscles The vocal fremitus at the bases may be diminished the percussion note impaired the breath sounds weak and accompanied by rhonchi crepitations or bubbling râles although these signs are for the most part due to the associated œdema In addition, the signs of the primary condition in the heart will be apparent

Complications —Pulmonary œdema and infarction are the chief complications

Diagnosis —This condition has to be distinguished from (1) chronic bronchitis in which case there may be some rise of temperature and the physical signs are more variable and more disseminated, (2) infarction in which pain and hæmoptysis of sudden onset are the rule

Course —If the venous engorgement cannot be removed it tends to become progressively worse whereas when it results from temporary cardiac embarrassment recovery is usually complete as soon as the heart function is restored

Prognosis —This is so entirely dependent upon the nature and degree of the condition responsible for the engorgement that no general rule can be formulated

Treatment —The treatment is that of heart failure with digitalis salt restriction and mercurial diuretics In elderly patients or those likely to be confined to bed for long periods, attention should be directed to the decubitus This should be changed frequently and if possible the patient should be permitted to sit up or to get into a chair and encouraged to take a few deep breaths several times during the day

(c) ACUTE OR HYPERACUTE PULMONARY ŒDEMA

In this condition flooding of the alveoli with the serous exudate from the pulmonary capillaries occurs with great rapidity

Ætiology —The most important cause of pulmonary œdema is left heart failure whether from hypertension disease of the aortic or mitral valves or coronary thrombosis Pulmonary œdema may also occur in acute cor pulmonale from pulmonary infarction It may complicate exposure to lung irritant gases or disease of the nervous system such as tumour vascular accident or trauma or intravenous transfusion or disturbance of the fluid balance in treatment with deoxycortone acetate (D O C A) cortisone or stilbœstrol Sometimes paracentesis of large effusions is followed by pulmonary œdema

Pathology —The alveoli are found to be flooded with a thin serous exudate The lungs are heavier than normal sodden and on squeezing exude large quantities

of greyish yellow or pinkish fluid Frothy fluid of similar character is found in the bronchi and even in the trachea and naso pharynx in hyperacute cases

Symptoms—The onset is sudden and generally occurs when the patient is lying down hence being most frequently observed at night The patient awakes with intense dyspnœa and a sense of suffocation then frequently rolls or rushes about in the endeavour to breathe even clutching at the throat Cyanosis is present and the aspect is one of anxiety and alarm Frothy fluid often pink in colour may soon stream from mouth and nose or be brought up in great gulps The chest movements are hurried and the accessory respiratory muscles are in violent action Vocal fremitus is diminished over the lower lobes The percussion note soon becomes impaired over the lungs commencing at the bases The breath sounds are at first vesicular or harsh with prolonged expiration then become faint and may be obscured by bubbling râles or crepitations audible all over the chest. Voice conduction is diminished

Complications and Sequelæ—Owing to its acute and rapid course complications do not occur Bronchitis may result as a sequela

Diagnosis—The affection is usually so characteristic that the diagnosis is obvious In the more protracted cases the dyspnœa and the physical signs are not unlike those of acute suppurative bronchitis or suffocative catarrh and broncho-pneumonia but in both of these there is some degree of fever and the expectoration is less copious and when it occurs is usually of purulent or muco purulent character The nocturnal onset of œdema may suggest asthma but the physical signs and the late and scanty expectoration in the latter suffice to distinguish it.

Course—The malady usually lasts only minutes or hours Unless it remits or treatment affords relief the patient rapidly becomes unconscious and death follows the heart continuing to beat after respirations have ceased

Prognosis—The prognosis is always very grave but prompt treatment has saved some cases *Death may occur in less than 10 minutes or be delayed for 24 or 48 hours*

Treatment.—The most successful treatment is the immediate subcutaneous injection of morphine gr $\frac{1}{4}$ Good results have also followed the injection of atropine sulphate gr $\frac{1}{100}$ to $\frac{1}{50}$ hypodermically Intravenous injection of aminophylline has been recommended The dose is 0 25 g in 10 ml of distilled water Oxygen inhalation by nasal catheter or the B L B mask or oxygen tent is of value in some cases others derive no benefit from it *Prompt venesection has been recommended*

(*d*) CHRONIC PULMONARY ŒDEMA

This is usually the sequel of chronic passive hyperæmia, and the causes and symptoms are those of that condition It may also occur in chronic renal disease In marked degrees of œdema, however the signs may closely simulate those of pleural effusion save for the displacement of the cardiac impulse It is important to remember that some degree of hydrothorax may occur as a complication and increase the difficulty in diagnosis

INFARCTION OF THE LUNGS

Infarction of the lungs or pulmonary apoplexy results when a branch of the pulmonary artery becomes occluded by embolism or thrombosis

Ætiology—*Embolic forms*—The obstructing plug may originate in any part of the systemic venous system in the right side of the heart or on its valves or in the pulmonary artery itself The commonest peripheral cause of embolism is detachment of a thrombus in cases of thrombo-phlebitis This may occur in the veins of

alveoli and in the fibroblasts in the inter alveolar septa In long standing cases the lung is firmer than normal and brownish red in colour a condition described as *brown induration* If any degree of œdema is present serous fluid is found in the alveoli on post mortem examination and on section of the lung frothy serous fluid exudes which may contain some of the pigmented alveolar cells constituting what are called cardiac cells ' Although congested and œdematous lung is heavier than normal, it usually floats in water

Symptoms —In slight degrees of hyperæmia these may be absent or negligible In more advanced cases they are those resulting from the impeded circulation through the lungs and the deficient aeration which this entails Dyspnœa is the most prominent symptom and it is generally a measure of the degree of hyperæmia It is markedly increased by exertion of any kind and in extreme degrees it is distressing and eventually alarming It may be inspiratory or expiratory in type, and in the latter case it is sometimes described as cardiac asthma In severe cases there is usually orthopnœa Cough is almost invariably present and there is usually some expectoration of frothy fluid, which may be blood stained The pigmented cells referred to above as cardiac cells may be found in it Cyanosis is common and indicates the degree of anoxæmia This may be associated with distension of the jugular veins and there is often obvious distress As in other forms of cyanosis there is usually some increase in the number of red corpuscles The vocal fremitus at the bases may be diminished the percussion note impaired the breath sounds weak and accompanied by rhonchi crepitations or bubbling râles although these signs are for the most part due to the associated œdema In addition the signs of the primary condition in the heart will be apparent

Complications —Pulmonary œdema and infarction are the chief complications

Diagnosis —This condition has to be distinguished from (1) chronic bronchitis in which case there may be some rise of temperature and the physical signs are more variable and more disseminated (2) infarction, in which pain and hæmoptysis of sudden onset are the rule

Course —If the venous engorgement cannot be removed it tends to become progressively worse whereas when it results from temporary cardiac embarrassment recovery is usually complete as soon as the heart function is restored

Prognosis —This is so entirely dependent upon the nature and degree of the condition responsible for the engorgement that no general rule can be formulated

Treatment —The treatment is that of heart failure with digitalis salt restriction and mercurial diuretics In elderly patients or those likely to be confined to bed for long periods attention should be directed to the decubitus This should be changed frequently and if possible the patient should be permitted to sit up or to get into a chair, and encouraged to take a few deep breaths several times during the day

(c) ACUTE OR HYPERACUTE PULMONARY ŒDEMA

In this condition flooding of the alveoli with the serous exudate from the pulmonary capillaries occurs with great rapidity

Ætiology —The most important cause of pulmonary œdema is left heart failure whether from hypertension disease of the aortic or mitral valves or coronary thrombosis Pulmonary œdema may also occur in acute cor pulmonale from pulmonary infarction It may complicate exposure to lung irritant gases or disease of the nervous system such as tumour vascular accident or trauma or intravenous transfusion or disturbance of the fluid balance in treatment with deoxycortone acetate (D O C A) cortisone or stilbœstrol Sometimes paracentesis of large effusions is followed by pulmonary œdema

Pathology —The alveoli are found to be flooded with a thin serous exudate The lungs are heavier than normal sodden and on squeezing exude large quantities

Symptoms—If a large embolus blocks one of the main divisions of the pulmonary artery there is sudden intense dyspnœa pain in the chest distress cyanosis and rapid unconsciousness death resulting in a few minutes from asphyxia In other cases the patient gives a short cry and falls unconscious death occurring almost immediately from syncope In some cases unconsciousness develops so rapidly and the respiratory symptoms are so little apparent that a cerebral vascular lesion may be suspected On the other hand life may be maintained for several minutes or even hours the patient being unconscious or in acute distress and anxiety with urgent dyspnœa lividity and cyanosis Respiration is deep and laboured but fails to give relief to the sense of suffocation In such cases also death may result eventually from asphyxia or syncope or the patient may slowly recover In less severe forms such as occur in cardiac and in some post operative cases there is sudden pain with difficulty in breathing followed in a few hours or in a day or two by cough with hæmoptysis or by the expectoration of deeply blood stained mucus persisting for some days and slowly clearing up If the embolus is infective fever often of hectic type results sometimes delayed for a day or more

In the severe cases there is cyanosis distension of the veins of the neck acute anxiety with exophthalmos and cold clammy skin The only physical signs apparent are the deep laboured breathing the harsh breath sounds and the evidence of cardiac embarrassment with feeble failing pulse

In less severe cases the signs are also not characteristic There are evidences of cyanosis and distress of less urgent character possibly some limitation of movement on the affected side increase of vocal fremitus localised dullness with weak or absent breath sounds and sometimes a pleural rub In some cases definite bronchial or tubular breath sounds may be audible A few fine râles are sometimes present in the adjacent lung areas

Complications and Sequelæ—Localised dry pleurisy is almost invariably present With infective emboli abscess or gangrene and later empyema may result In organisation an infarct leads to a localised area of fibrosis

Diagnosis—The dramatic onset the history and the associated lesions of the veins or heart render diagnosis easy as a rule but it may be necessary to eliminate other causes of hæmoptysis notably pulmonary tuberculosis and chronic venous hyperæmia

Radiological appearance—It is possible to have an extensive infarction without any visible radiological change and in fact it is usually the smaller lesions which can be seen in the form of small peripheral areas of opacity not very clearly defined and occasionally associated with pleural effusion The diaphragm may be raised

Course—As already described death may occur from asphyxia or syncope in the course of a few minutes or hours although recovery occurs in some very severe cases In the less severe forms after the initial urgent symptoms have passed off recovery is often rapid and uneventful save for pain cough and blood stained expectoration

Prognosis—This depends largely upon the initial shock The prognosis is very grave when the patient rapidly becomes unconscious As there is less likelihood of sepsis in cases due to cardiac lesions than in those due to localised venous thrombosis the prognosis is rather better in the former but on the other hand organisation of a clot in a vein may completely remove the source of the emboli while the source often persists when they are derived from the heart

Treatment—Morphine pethidine or papaverine should be given to allay the anxiety of the patient Atropine gr $\frac{1}{100}$ or $\frac{1}{60}$ is often given but is of doubtful value Anti coagulant therapy should be given to prevent further spread and formation of clot Heparin should be given intravenously in doses of 5000 units 4 hourly for 24 hours One of the dicoumarol derivatives such as ethyl biscoumacetate (Tromexan) or phenylindanedione (Dindevan) should be started at the same time

the lower extremity, or in those of the uterus after childbirth Thrombosis with embolic detachment may also develop in prolonged or wasting diseases such as enteric fever tuberculosis and cancer in acute processes such as influenza, septicæmia and pyæmia and in localised septic lesions such as otitis Pulmonary embolism is not infrequently observed after abdominal or pelvic operations, and after the radical cure of hernia or hæmorrhoids

Intracardiac thrombi from the right auricle or ventricle becoming detached lead to embolism and this occurs especially in cases of right sided heart failure secondary to left sided valve lesions Vegetations forming on the tricuspid or pulmonary valves in septic endocarditis on detachment produce pulmonary infarction Rarer causes are fat embolism after injury to bone or to a fatty liver, the entry of pieces of new growth or hydatid daughter cysts into systemic veins and even air embolism occurring sometimes as a complication of pneumoperitoneum It may also occur during blood transfusion if the pressure in the bottle is raised unduly by a Higginson s syringe while the filter is partially blocked Air embolism has followed insufflation of the vagina with silver picrate powder in the treatment of vaginitis and trichomonas infections

Thrombotic forms —Thrombosis occurs as a secondary process around pulmonary emboli but it is probable that some cases of infarction are due to a primary thrombosis This condition may be produced by some acute or chronic pulmonary disease, such as gangrene tuberculosis and fibrosis and by atheroma of the pulmonary artery Any process leading to chronic venous hyperæmia may also cause it A rare cause is thrombo phlebitis migrans

Pathology —Although the pulmonary arteries are not strictly speaking end arteries since there is some degree of anastomosis between them and the bronchial arterioles yet the result of their obstruction is to produce infarcts comparable with those in other organs The origin of the blood in the obstructed area has been much discussed Cohnheim regarded it as the result of regurgitation from the veins a view subsequently disproved since the infarct is hæmorrhagic even when the veins are also obstructed It is now regarded as due to influx from the anastomosing bronchial capillaries into the pulmonary capillaries and the escape of this blood from the latter owing to their altered nutrition It is generally accepted that embolism is much more common than thrombosis If a large embolus has caused sudden death it will be found arrested at the bifurcation of a large branch of the pulmonary artery or even in one of the main divisions of that vessel In such cases there has not been time for pulmonary changes to occur and the chief post mortem condition found is engorgement of the right side of the heart

In post mortem examination of cases where smaller emboli have led to infarction the infarcts are usually found in the lower lobes more commonly in the right lung They extend to the surface in the majority of cases and can be seen before section as slightly raised dark red areas with the overlying pleura a little roughened from inflammatory exudate They feel hard and firm and on section are typically wedge shaped with the base on the surface and the apex centrally placed In the rare deep seated infarcts a spheroidal form is the rule When recent an infarct is dark red in colour and suggests hæmorrhage with clot formation hence the term pulmonary apoplexy In some cases infarcts have a purplish hue and are said to resemble the colour of damson cheese later they change to brownish red Infarcted areas sink in water There may be a single large infarct almost occupying one lobe sometimes only a small one or several of varying size and age scattered throughout the lungs In some cases a fortunate section may reveal the embolus with its ensheathing thrombus but sometimes a thrombus only is found Microscopically the alveoli and finer bronchioles are filled with red blood corpuscles and there is a sharp delimitation from the healthy lung If the embolus is infective suppuration occurs and abscess or empyema ensues

The general consensus of opinion now is that collapse is due to bronchial obstruction produced by plugs of mucus foreign bodies or by swelling of the mucous membrane bronchial spasm or external pressure Paralysis of the diaphragm to which Pasteur gave the premier role does not of itself produce massive collapse although immobility or elevation of the diaphragm favours the formation of obstructive plugs on the one hand and on the other may be the result of the obstruction and consequent collapse

Synonyms —Active Lobar Collapse Massive Collapse

Ætiology —The causes are many and various Foreign bodies in the bronchial tree neoplasms of the bronchus granulomata usually tuberculous stenosis of the bronchus as a result of tuberculosis syphilis or bronchiectasis form an endobronchial group Compression of a bronchus by mediastinal tumours aneurysms or pericardial effusions form another

Then there is the much larger group of post operative and post traumatic cases and those occurring in whooping cough bronchitis asthma pneumonia and bronchiectasis In all these cases the probable common factor is obstruction by retained secretions

Barium included in post operative feeds and lipiodol inserted into the mouth during dental operations has shown that pulmonary aspiration is much commoner after operations than is generally realised

Collapse due to fluid in the bronchial tubes blood lipiodol liquid paraffin and sea water are specially mentioned because they tend to be forgotten

Collapse of the lung which frequently follows the division of adhesions in artificial pneumothorax is probably due to the trapping of retained secretion to bronchial stenosis or ulceration or a combination of these factors

Pathology —At post mortem examination the whole of the lung or a lobe or portion of a lobe may be deflated and retracted towards the hilum The collapsed area is bluish red firm does not crepitate and sinks in water There are often pneumonic and pleuritic changes but these may be either primary or secondary

In massive collapse the heart and mediastinum are displaced towards the affected side and the unaffected lobes are distended with air

Symptoms —The abruptness of onset depends on the causation and the extent of collapse Massive collapse of the whole lung and of a whole lower lobe following operation usually has a sudden onset with pain in the lower part of the thorax and behind the sternum Severe dyspnœa quickly follows and the patient appears dusky cyanosed and alarmingly ill There may be a cough but it is often unproductive The pulse and respiration rate are rapid and the temperature often rises abruptly Occasionally especially in old people the onset is more surreptitious

The physical signs of massive collapse are usually dramatic There is immobility of the affected side often with sucking in of the ribs The apex beat is displaced towards the affected side There is dullness to percussion on the affected side with hyper resonance on the unaffected The vocal fremitus is diminished or absent and the breath sounds are diminished or absent Occasionally conduction is increased with bronchial breathing and only the displacement of the apex beat and trachea gives a clue to the true diagnosis but if the obstruction is in a main bronchus these physical signs are unlikely Hilar or lobular collapse will give proportionately less physical indications

Radiological appearances —The radiological appearances are characteristic but vary with the extent and duration of the collapse There will be a homogeneous opacity varying in shape with the lobes involved accompanied by local and general compensatory emphysema deviation of the trachea and heart to the side of the lesion and elevation of the diaphragm Lateral or oblique views are essential

Complications and Sequelæ —These depend on the cause of the obstruction and vary from broncho pneumonia and pulmonary abscess to pleurisy and empyema

Tromexan 0 3 g , is given three times during the first day and after that three times a day in a dose controlled by prothrombin estimation Dindevan 0 1 g is given morning and evening for the first day and subsequently twice daily in doses controlled by daily prothrombin estimations After the prothrombin time has been brought to between 20 and 30 per cent of normal, heparin is discontinued and Tromexan or Dindevan is continued in controlled doses The danger of spontaneous *hæmorrhages* must be borne in mind *Pulmonary embolectomy has been successfully* performed, but unless the services of a surgeon with special knowledge of cardio vascular surgery are available the patient is more likely to survive if recovery is left to nature

The danger of too *great immobilisation of patients especially elderly ones,* must be borne in mind and whenever possible patients should be allowed to get out of bed for toilet purposes or allowed to sit in a suitable chair at intervals or limb exercises should be regularly performed under supervision

COLLAPSE OF THE LUNGS

In collapse of the lungs the alveoli are completely or partly devoid of air The *condition may be congenital and due to non expansion of the lung* when it is re ferred to as atelectasis On the other hand, collapse may be the result of removal of the air from lung tissue previously expanded, when it is called apneumatosis or acquired collapse The three terms—collapse atelectasis and apneumatosis—are however used as *synonyms by many writers*

ATELECTASIS OR CONGENITAL COLLAPSE

Ætiology—This condition occurs in still born and in premature infants and probably persists to some degree for weeks or even months in weakly children *It* may result from immaturity or from weakness of the inspiratory muscles and from obstruction of the air passages by mucus and meconium It may be a consequence of disease such as congenital syphilis or lesions and developmental defects of the *nervous system*

Pathology—Atelectasis is due to failure of the respiratory mechanism to draw air into the alveoli and expand them as occurs normally with the first few inspiratory efforts of the newborn infant

Atelectatic lungs are solid airless and small They are usually described as presenting appearances similar to those of adult liver as regards colour and consistence In partial atelectasis the lung appears mottled and small expanded areas of pinkish colour may project from the surface The condition is chiefly of medico legal and pathological interest

APNEUMATOSIS OR ACQUIRED COLLAPSE

There are two types of acquired collapse That due to obstruction of some part of the bronchial tree and that due to external pressure by fluid, air or diaphragmatic abnormalities These two conditions have previously been described as active and passive collapse respectively but Pasteur, who described collapse in a Bradshaw Lecture in 1908, used these terms in quite a different sense since he described as active , collapse which he thought was due to diaphragmatic paralysis and he used the term 'passive *to describe lobular collapse due to bronchial* obstruction The terms are best avoided This latter type of collapse is sometimes known as absorption collapse as opposed to relaxation or compressive collapse where the primary cause of the collapse is outside the bronchial tree

Tromexan 0 3 g , is given three times during the first day and after that three times a day in a dose controlled by prothrombin estimation Dindevan 0 1 g, is given morning and evening for the first day and subsequently twice daily in doses controlled by daily prothrombin estimations After the prothrombin time has been brought to between 20 and 30 per cent of normal heparin is discontinued and Tromexan or Dindevan is continued in controlled doses The danger of spontaneous hæmorrhages must be borne in mind Pulmonary embolectomy has been successfully performed but unless the services of a surgeon with special knowledge of cardiovascular surgery are available the patient is more likely to survive if recovery is left to nature

The danger of too great immobilisation of patients especially elderly ones must be borne in mind and whenever possible patients should be allowed to get out of bed for toilet purposes or allowed to sit in a suitable chair at intervals or limb exercises should be regularly performed under supervision

COLLAPSE OF THE LUNGS

In collapse of the lungs the alveoli are completely or partly devoid of air The condition may be congenital and due to non expansion of the lung when it is referred to as atelectasis On the other hand collapse may be the result of removal of the air from lung tissue previously expanded when it is called apneumatosis or acquired collapse The three terms—collapse atelectasis and apneumatosis—are however, used as synonyms by many writers

ATELECTASIS OR CONGENITAL COLLAPSE

Ætiology—This condition occurs in still born and in premature infants and probably persists to some degree for weeks or even months in weakly children It may result from immaturity or from weakness of the inspiratory muscles and from obstruction of the air passages by mucus and meconium It may be a consequence of disease such as congenital syphilis or lesions and developmental defects of the nervous system

Pathology—Atelectasis is due to failure of the respiratory mechanism to draw air into the alveoli and expand them as occurs normally with the first few inspiratory efforts of the newborn infant

Atelectatic lungs are solid airless and small They are usually described as presenting appearances similar to those of adult liver as regards colour and consistence In partial atelectasis the lung appears mottled and small expanded areas of pinkish colour may project from the surface The condition is chiefly of medico legal and pathological interest

APNEUMATOSIS OR ACQUIRED COLLAPSE

There are two types of acquired collapse That due to obstruction of some part of the bronchial tree and that due to external pressure by fluid air or diaphragmatic abnormalities These two conditions have previously been described as active and passive collapse respectively but Pasteur who described collapse in a Bradshaw Lecture in 1908 used these terms in quite a different sense since he described as active collapse which he thought was due to diaphragmatic paralysis and he used the term passive to describe lobular collapse due to bronchial obstruction The terms are best avoided This latter type of collapse is sometimes known as absorption collapse as opposed to relaxation or compressive collapse where the primary cause of the collapse is outside the bronchial tree

HÆMOPTYSIS

It should be recognised that hæmoptysis is a symptom not a disease It is here considered separately because the accurate diagnosis of its origin is essential to its treatment which differs widely in different conditions

Definition—The term hæmoptysis is arbitrarily restricted to the expectoration of blood entering the air passages from structures below the larynx or from the larynx itself When the blood is derived from the naso pharynx or mouth it is sometimes described as spurious hæmoptysis

Ætiology—1 Pulmonary tuberculosis is the commonest cause, the blood being derived from an aneurysm in a pulmonary cavity or from ulceration of a small vessel or congestive processes around the early lesions

2 Chronic venous congestion particularly in mitral stenosis

3 Bronchiectasis as a result of bleeding from granulation tissue or from ulceration of the bronchiectatic walls Latent bronchiectasis without sputum may cause recurrent hæmoptysis (*forme hemoptoique sèche*) this is more common in upper lobe bronchiectasis

4 Inflammatory and destructive diseases of the lungs air passages or pleura such as pneumonia broncho pneumonia especially the influenzal variety abscess and gangrene Pneumoconiosis streptotrichosis and ulceration of the larynx trachea or bronchi from tuberculosis gumma or new growth may also be associated with hæmoptysis Breaking down of a caseous or calcareous bronchial gland is a rare cause as also is rupture of an empyema through a bronchus

5 Infarction of the lung from embolic or thrombotic obstruction

6 New growths of the lung bronchi or mediastinal glands

7 An aortic aneurysm may cause hæmoptysis by weeping through an eroded bronchus or by direct rupture the latter being of course immediately fatal

8 Traumatic causes—Injury may cause hæmoptysis by fractured ribs wounding the lung by contusion and by breaking down of healed tuberculous lesions Hæmoptysis occurs frequently in wounds of the chest both penetrating and non penetrating A foreign body such as a piece of shrapnel may lie dormant for years and then cause recurrent hæmoptysis

9 Certain abnormal blood conditions chiefly leukæmia purpura hæmophilia scurvy minor degrees of vitamin C deficiency and occasionally pernicious anæmia Hæmoptysis occasionally occurs in the malignant specific fevers especially small pox and measles

10 Parasitic causes such as pulmonary distomatosis and spirochætosis are common in Asia but rare in Europe Hydatid disease of the lung may cause repeated slight hæmorrhages

11 Vicarious menstruation—Some cases in women have been regarded as vicarious menstruation and this view dates back to Hippocrates It is probable however that most cases are to be explained as due to leakage from obscure pulmonary lesions

12 Hæmoptysis occasionally occurs in apparently healthy persons In some with high systemic arterial tension it is probable that the pulmonary arterial pressure is also raised and the condition may be regarded as analogous to the epistaxis which occurs more commonly in such patients Sometimes the hæmoptysis is due to leaking from an old arrested tuberculous lesion

13 Rupture of an hepatic abscess or hydatid cyst through the diaphragm into a bronchus is an occasional cause

14 Polyarteritis nodosa is a rare cause of pulmonary hæmorrhage

Spurious hæmoptysis is usually due to staining of the saliva or the pharyngeal secretion with blood generally derived from the gums which are spongy and congested often from early pyorrhœa The condition is common in anæmic girls and

Post operative cases which survive the abrupt onset usually make a complete recovery when the obstructing mucus is coughed up

Diagnosis —The most important conditions from which this malady has to be distinguished are lobar pneumonia pulmonary embolism pneumothorax and pleural effusion The position of the cardiac impulse is often the deciding factor in collapse it is displaced towards the lung involved, in pleural effusion and pneumothorax it moves away from the affected side whereas in lobar pneumonia there is usually no cardiac displacement, although there may be dilatation Labial herpes and blood stained expectoration are more frequently seen in pneumonia than in collapse When in right sided collapse there is marked distension of the left lung with obliteration of the normal cardiac dullness the signs superficially resemble those of a left sided *pneumothorax*, but with *careful examination no such error should be made* The distinction from pulmonary embolism may be difficult at first but the localisation of the signs and the blood stained expectoration may give useful indications

Course —The course of the affection in post operative cases or cases associated with bronchitis asthma or lobar pneumonia is rapid After periods extending from *2 to 5 days the temperature falls to normal the symptoms disappear the lung* quickly re expands the heart returns to its normal position and there is complete recovery

Treatment —Prophylactic treatment prevents the onset of post operative collapse Planned operations should not be carried out on patients with acute respiratory infections or with untreated suppurative conditions of the naso pharynx Patients should be encouraged to sit up and move as soon as possible after operation Those found to have poor pulmonary ventilation before operation should be taught breathing exercises which will be of service both before and after operation Once the collapse has occurred the object of treatment is to produce cough and expectoration and restore ventilation to the collapsed lung Tight abdominal binders or strapping should be loosened the patient laid flat on his back and gently rolled from side to side twelve times This often results in cough with expectoration of the obstructing mucus and the lung rapidly re expands This treatment (Sante manœuvre) should be repeated every 4 hours if it is not successful at the first attempt It is surprising how rapidly relief can be obtained by this simple manœuvre even in cases in which the collapse has been present for 2 or 3 days Stimulant expectorants should be given subsequently for a few days Postural drainage should be used and tapotage over the affected lung sometimes helps to dislodge the mucus and promote effective coughing Inhalation of oxygen with 7 per cent of carbon dioxide promotes deep respiration Accurate measurements of the daily sputum should be kept A diminution without clinical improvement is suggestive of recurrence of the obstruction Bronchoscopic aspiration has been recommended in cases of post operative massive collapse Usually no plugs of mucus are seen obstructing the collapsed bronchus

Collapse due to External Pressure —Pleural effusions pneumothorax and diaphragmatic displacement also produce collapse of the lung The latter operates by alveolar compression The first two operate by separating the two layers of the pleura and allowing the lung to retract This first stage is known as relaxation collapse Large effusions or pressure pneumothoraces cause compression collapse which is more complete High tension pneumothoraces in patients with a mobile mediastinum sometimes cause collapse of the peripheral portion of the contralateral lung This form of collapse is described with the conditions which cause it

COMPLETE CONGENITAL ABSENCE OF A LUNG

Complete congenital absence of a lung is a rare condition *but can be diagnosed* by radiographic examination *It is not* compatible with a normal expectation of life

While distinguishing between the various causes of hæmoptysis it is well to regard and to treat it as due to pulmonary tuberculosis until some other cause is conclusively established The sputum should be examined for tubercle bacilli on several occasions the temperature recorded and the physical signs including radio graphic appearances most carefully watched

The presence of a valvular lesion especially mitral stenosis with signs of pulmon ary engorgement may render the cause of hæmoptysis clear When tuberculosis and cardiac disease can be excluded a careful study of the history the symptoms and signs may throw light on the diagnosis or suggest some investigation which will serve to establish it *e g* examination of the sputum for parasites and hydatid hooklets the cytological examination of the blood and radiographic examination

In other cases as in bronchiectasis abscess or gangrene the history, the physical signs and the nature of the sputum are often characteristic

In the latent or silent form of bronchiectasis (*forme sèche*) the condition may be revealed only by lipiodol injection

Bronchoscopy may be of great value in revealing the presence of adenoma or carcinoma Patients who have had a hæmoptysis which has eluded diagnosis must be kept under observation with radiographic control

Prognosis —Apart from hæmoptysis due to aneurysm which is rapidly fatal or pulmonary tuberculosis the immediate prognosis in cases of pulmonary hæmor rhage is not unfavourable even when it continues for days The ultimate prognosis depends upon the cause

Treatment —This is so entirely dependent upon the cause and origin of the bleeding that reference should be made to the corresponding diseases

EMPHYSEMA OF THE LUNGS

Emphysema of the lungs or alveolar ectasis is a condition of distension of the alveoli it is usually progressive and is associated with definite changes in the inter alveolar walls The following varieties are generally recognised—(1) large lunged or hypertrophic (2) small lunged or atrophic (3) compensatory (4) acute vesicular and (5) acute interstitial emphysema The last named condition has no relation to true emphysema except in name but will be described in this group for convenience

1 LARGE LUNGED OR HYPERTROPHIC EMPHYSEMA (SUBSTANTIVE OR IDIOPATHIC EMPHYSEMA)

This is a chronic affection and is usually bilateral

Ætiology —*Predisposing causes* —It may occur at any age even in childhood but is most frequently seen in middle and late adult life It is commoner in men than in women probably because they are more exposed to the conditions inducing it Although not strictly hereditary it often shows a familial incidence Certain occupations are credited with being concerned in its production notably those in volving violent or prolonged muscular effort with closed or partially closed glottis such as blowing wind instruments and lifting heavy weights Dusty occupations also favour its onset by leading to bronchitis and cough

The common *exciting cause* seems to be the strain of prolonged and repeated cough induced by chronic bronchitis bronchiectasis asthma whooping cough cigarette smoke inhaling and other causes of irritation of the upper air passages

Pathology —The pathogenesis of emphysema has been much debated and various explanations have been offered (1) Primary degeneration theory Villemin sug gested that the essential lesion was a fatty degeneration of the alveolar walls while Cohnheim believed that there was a congenital defect of the elastic tissue of the lung

is as a rule observed in the morning Hæmorrhage from an enlarged pharyngeal vein is often suggested as a cause but is rarely seen Hæmorrhage after tooth extraction and staining of the mucus expectorated after epistaxis are other causes of spurious hæmoptysis

Pathology —From the list of causes it might be inferred that the origin of the blood differs in different cases It may come from the pulmonary or bronchial vessels in pulmonary tuberculosis and other lung or bronchial conditions, and also in chronic venous congestion or infarction It may come from the thoracic aorta direct or from some of its branches in aneurysm and mediastinal new-growth and from the hepatic vessels in abscess of the liver In cases due to disease of the trachea and larynx it comes direct from the vessels supplying them

Post mortem the larynx trachea and bronchi may contain clots or blood stained froth and mucus and their walls may be stained in places Dark reddish areas of lobular distribution due to inhaled blood may be seen in various parts of the lungs particularly at the bases Sometimes this may induce bronchitic changes described as hæmoptoic bronchitis Careful search in cases of profuse hæmoptysis will usually reveal the source of the hæmorrhage and in pulmonary tuberculosis this is generally a ruptured aneurysmal dilatation in a cavity or an ulcerated vessel The aneurysm may be small and escape notice unless many cuts are made into the lung

Symptoms —In hæmoptysis the patient often experiences a tickling in the throat followed by a gush into the mouth with a salt taste and on expectoration notices blood The alarm and anxiety this occasions lead to restlessness and rapid action of the heart If the bleeding is profuse cough is frequent and large clots together with liquid alkaline blood may be expectorated to the extent of 20 or 30 oz in a few hours The bleeding may cease temporarily to recur at intervals for several days until the patient becomes blanched weak and syncopal with rapid weak pulse In any profuse hæmoptysis death may occur in a few minutes either from asphyxia or syncope In the former case the blood at first bright and arterial is soon dark and frothed while the patient becomes cyanosed and livid In slighter degrees of hæmoptysis there may be only streaks small clots or liquid blood mixed with ordinary sputum After the actual bleeding has ceased the sputum may be blood stained for some days owing to the expectoration of blood inhaled into other parts of the lungs This can be recognised by its colour which varies from dark red to brown owing to the changes undergone by the blood pigment

Diagnosis —This involves two problems—first the differentiation from hæmatemesis and spurious hæmoptysis and secondly the recognition of the cause of the hæmorrhage If the patient is seen at the time of the bleeding the first of these is easy The nature of the blood and its association with cough and possibly with pulmonary or cardiac signs are conclusive When the diagnosis has to be made upon the history given by the patient or by friends it may be difficult especially in the absence of physical signs

In hæmatemesis there is frequently gastric pain and faintness before the vomiting the blood is acid in reaction dark in colour even brown from acid hæmatin and is sometimes mixed with food The fact that in hæmoptysis blood may be swallowed and subsequently vomited increases the difficulty Patients often give very dubious answers to questions as to whether the blood was coughed or vomited up They should then be questioned as to whether sputum was brought up on the following day and if so whether it was blood stained In cases of doubt the investigation of the pulmonary and abdominal physical signs when the patient s condition permits may decide the diagnosis

The utmost caution should be exercised to exclude tuberculosis before making a diagnosis of spurious hæmoptysis Only when there are no pulmonary symptoms signs or radiographic indications and when some obvious cause such as anæmia or pyorrhœa is found is it safe to do so

is common and is to some extent a measure of the degree of emphysema Varying degrees of polycythæmia may be observed The patient may walk about with a more extreme degree of cyanosis than in any other condition except congenital heart disease Clubbing of the fingers of moderate degree is common Cough is usually due to the associated bronchitis and is worse in the winter and in foggy weather It is frequent noisy and often hacking and paroxysmal Expectoration is also the result of the bronchial catarrh and varies from a few grey mucoid pellets to copious muco pus

The chest is enlarged particularly in the antero posterior diameter, the upper thoracic spine is rounded and kyphotic the sternum protrudes forward and the *angle of Louis is prominent the general effect being the so called barrel shaped chest* The ribs run forward more horizontally and the intercostal spaces are wider than normal the chest being as a whole in the inspiratory position The respiratory movements are much restricted the patient elevating the rigid thorax with little expansion on taking a deep breath so that the inspiratory increase at the level of the nipples may be only ½ to 1 inch instead of the normal 2½ to 3 for an adult. There is often filling and even bulging of the supra clavicular hollow while the neck appears short the sternomastoids stand out and the jugular veins are full A zone of dilated *venules the emphysematous girdle is often present along the line of the costal* attachment of the diaphragm but is not pathognomonic The cardiac impulse is not visible as a rule and may only be felt with difficulty, but epigastric pulsation is usually apparent Vocal fremitus is diminished and the percussion note is hyper resonant The superficial cardiac dullness is greatly diminished or even absent and the lower limit of pulmonary resonance may extend to the costal margin back and front the hepatic dullness being encroached on or obliterated

It is said that in bullous emphysema the breath sounds are harsh over the outer part of the upper lobes in front and weak at the bases In general emphysema the breath sounds are weak everywhere inspiration is short and expiration is greatly prolonged A loud rumbling from contraction of the thoracic muscles may entirely obscure the breath sounds A few fine bubbling râles may be heard at the bases or at the sternal margins If bronchitis is present scattered rhonchi may be audible Vocal resonance is generally slightly diminished The heart sounds are weak and distant and in late stages a tricuspid systolic murmur may develop The vital capacity of the lungs measured by a spirometer is often reduced to one half or less Radiographic examination shows increased extent and undue translucency of the lung tissue It shows the diaphragm lower in position and flattened and the costophrenic angle widened The liver is sometimes palpable possibly from down ward displacement by the bulky lung The spleen may also be depressed and palpable

Complications—Bronchitis is the commonest and often causes a vicious circle Asthmatic attacks so called bronchial asthma are common in later stages on the other hand spasmodic asthma may be the cause of the emphysema Pneumo-thorax and interstitial emphysema may occur from rupture of the bullæ although these accidents are relatively rare or perhaps relatively rarely diagnosed since the difficulties of diagnosis in these cases are obvious Pneumothorax is a common com plication of the severe emphysema of advanced pneumoconiosis Pulmonary tuber culosis is an occasional complication of emphysema which contrary to popular opinion is not antagonistic to it although it may mask and obscure the early stages Right sided cardiac failure with its train of consecutive changes is a late and often terminal complication

Diagnosis—This is never difficult in advanced cases The slighter degrees may be more difficult and the diagnosis is then largely a matter of inference from the association of chronic cough and dyspnœa with physical signs of hyper resonance and prolonged expiration

Confusion may occasionally arise with pneumothorax and pulmonary tuberculosis

(2) The inspiratory theory first suggested by Laennec and developed by Gairdner postulates *the force of inspiration as the distending* agent (3) The expiratory theory first enunciated by Mendelssohn was independently brought forward and established by Jenner The distension of the alveoli is regarded as due to the effect of forced expiration and cough Jenner pointed out the special and early involvement of the apices the anterior and lower margins of the lungs in other words the parts least supported by the thoracic cage (4) Freund regarded the changes in the lungs as secondary to calcification of the costal cartilages the chest becoming fixed in the inspiratory position and the lung permanently expanded in consequence Christie in an analysis of these and other theories concludes that there are probably three factors of importance inflation of the lungs caused by obstruction to expiration, loss of elasticity due to the stress and strain of coughing in asthma, lowered resistance of the lung to wear and tear varying from person to person and becoming progressively lower with advancing age

The characteristic conformation of the chest is usually apparent (see Symptoms) the costal cartilages are often calcified and on opening the thorax post mortem the lungs bulge instead of retracting, so that the pericardium may be almost completely obscured They are pale in colour even in town dwellers a condition called albinism of the lung by Virchow They are soft and pit on pressure, and as described by Laennec give the sensation of a down pillow The surface of the lung under the pleura shows a finely vesicular appearance due to the distension of the alveoli the vesicles often being nearly as large as pins heads Not infrequently large bullæ or blister like protuberances, varying in size from a pea to a Spanish olive, occasionally much larger may be seen projecting from the surface particularly at the apices and margins These bullæ when incised show fine fibrous bands crossing them the remains of inter alveolar walls and of atrophied blood vessels It was formerly customary to refer to such cases as bullous or marginal emphysema and to describe those in which the dilatation is less obvious but more widely diffused as general emphysema, but the conditions are so commonly associated together in varying degrees that little is gained by so doing On section the lungs are pale and dry except at the bases where there is frequently some œdema in advanced cases The bronchi may show some general dilatation When bronchitis coexists muco pus can be squeezed from the cross sections of these tubes As pointed out by Fowler pleural adhesion is relatively uncommon The infundibula and alveoli are dilated and the inter alveolar walls are thin and atrophic even disappearing wholly or in part The distension and coalescence of adjacent alveoli result *in the formation* of bullæ The calibre of the pulmonary capillaries is diminished by stretching of the alveolar walls, and where atrophy of the inter alveolar septa occurs the capillaries are destroyed These two processes result in a *considerable diminution* in the total aerating surface and cause the dyspnœa and cyanosis characteristic of the disease Moreover the normal anastomoses between the terminal bronchial and pulmonary capillaries *increase considerably* and *some of the blood in the* latter may therefore fail to reach the alveoli and so escape aeration Atrophic changes in the elastic tissue have been described In order to maintain the circulation through the diminished *capillary area the right ventricle hypertrophies and the resultant* raised blood pressure sometimes induces atheroma of the pulmonary artery Emphysema being a progressive lesion and the defective aeration of the blood perhaps interfering with the *nutrition of the heart muscle* cardiac failure eventually ensues causing tricuspid regurgitation engorgement of the right auricle and the visceral effects of venous engorgement such as ' nutmeg liver

Symptoms —Dyspnœa of varying degree is the most characteristic symptom In uncomplicated cases of moderate extent it is only present on exertion unless bronchitis coexists In advanced emphysema dyspnœa is marked and becomes extreme in the bronchitic or asthmatic attacks and in foggy weather Cyanosis

general atrophy and debility There is shortness of breath only on exertion or on exacerbation of the chronic bronchitis which is frequently present The chest is small flat and thinly covered the movements are poor and there is elevation of the chest as a whole with poor expansion Kountz and Alexander maintain that there is very little diminution in vital capacity that the movements of the diaphragm are increased and that the intervertebral disks are abnormal There is little cyanosis and no clubbing The vocal fremitus is unaltered or slightly diminished The percussion note is hyper resonant but there is no encroachment on the cardiac and hepatic areas of dullness Breath sounds are weak, and there is but little prolongation of expiration Rhonchi and râles may be heard especially if bronchitis is present, or if the heart is failing

Diagnosis—The condition is generally so obvious that no difficulty arises

Treatment—This is chiefly a matter of careful regimen and diet with treatment of co existing bronchitis or cardiac failure

3 COMPENSATORY EMPHYSEMA (LOCALISED OR SECONDARY EMPHYSEMA)

Ætiology—Localised emphysema is a sequel to some process inducing collapse contraction or destruction of areas of lung tissue It may be lobular in distribution in bronchitis broncho pneumonia tuberculosis and diphtheria It may affect one or more lobes or the whole of one lung especially in cases of fibrosis following tuberculosis pneumonia chronic pleural effusion and empyema

Pathology—It is generally conceded that the inspiratory theory of Laennec and Gairdner satisfactorily explains the genesis of this condition When shrinkage of an area of lung occurs the chest wall may fall in if there is pleural adhesion but otherwise inspiration tends to expand the normal parts of the lungs None the less it must be admitted that the expiratory strain of cough may assist in its production

Although it may be compensatory and physiological at its inception it is doubtful whether a true hypertrophy takes place after adolescence In any case it soon leads to atrophy of the alveolar walls as in true emphysema and thus becomes pathological and harmful Post mortem the condition may be found in an upper lobe around contracted scarred lung tissue or in a lower lobe when the upper lobe is contracted or disorganised In cases where one lung is fibroid and contracted compensatory emphysema may be found throughout the sound lung The resulting adaptations caused by enlargement of one part and shrinking of another may produce some striking displacements the lower lobe extending upwards nearly to the clavicle or the anterior margin of the sound lung crossing the mid line The general appearances are closely similar to those of ordinary emphysema except that bullæ do not occur at any rate until the process is advanced and definitely pathological

Symptoms—This condition does not produce symptoms that can be differentiated from those of the primary disease When it affects a lobe or the whole of one lung there is hyper resonance over the area involved which often contrasts strikingly with the dullness due to the primary lesion The hyper resonance may extend across the sternum and even for an inch or more beyond it. The heart is displaced towards the side where fibrosis is in progress Vocal fremitus and vocal resonance are little altered but may be increased at first and subsequently diminished In the early stages when there is alveolar dilatation without degenerative mural changes the breath sounds are exaggerated harsh or puerile but when such processes develop they become weak and there are indications of dyspnœa and cyanosis on exertion

Diagnosis—This is easy owing to the difference between the diseased and compensatory areas and to the indications of contraction and displacement

Treatment—No special treatment apart from that of the primary condition is required

Dr PC ... RAR

Careful record of the symptoms and signs and the investigation of the sputum generally suffice to distinguish these conditions In doubtful cases radiography will assist

Course—Emphysema is progressive unless the cause is removed or the effects of the disease are mitigated by residence in a warm dry climate especially in the winter Conversely, residence in unsuitable districts, persistence in detrimental employment and repeated attacks of bronchitis accelerate its course

Prognosis—This depends upon the degree of emphysema and the circumstances of the patient If progressive it exerts an increasingly crippling effect and it certainly shortens life under urban conditions A '*vital capacity* *of less than 50 per cent* of the normal is of serious import The advent of severe bronchitis or of cardiac complications may affect the prognosis gravely

Treatment—Emphysema may be arrested but cannot be cured Attention must *be directed to prevention of the causes of chronic cough and increased intra alveolar* tension In any person with hereditary tendency to emphysema or to winter cough the questions of occupation and place of residence should be carefully considered When the disease is established, the patient, if in a position to afford it, should spend the winter in a warm more equable climate either abroad or at the south west coast of England

Various attempts have been made to increase the respiratory ventilation of the lungs by deflation The most generally used method is by the use of a well fitting abdominal belt to raise the diaphragm Efforts in the same direction have been made by pneumoperitoneum and even pneumothorax Their justification is doubtful

Expiration breathing exercises are of general application and quite impressive results can be obtained by their use provided the chest wall is not completely rigid Even in these cases diaphragmatic movement can be increased

The diet should be simple and easily digestible especially in the later stages If there is spasmodic dyspnœa or asthma no late meal should be permitted Clothing *should be warm but the excess of under garments often worn in fear* of chill is harmful Patients should avoid those who have colds and should themselves stay in bed at the first sign of such an infection in themselves

In other respects treatment is largely symptomatic In acute bronchitic attacks *the measures to be adopted are in no way different from those in bronchitis un*complicated by emphysema In the more chronic bronchitis so commonly present in the winter iodides with alkalis and balsamic expectorants seem beneficial When asthma or paroxysmal dyspnœa occurs antispasmodic drugs and measures similar to those used in spasmodic asthma may be employed When cardiac failure supervenes the appropriate treatment must be vigorously applied If there is marked cyanosis and venous engorgement oxygen administration and diuretic drugs may be employed, and digitalis administered any associated pulmonary infection even bronchitis requires energetic treatment with the appropriate antibiotic *broncho*spasm should be treated with antispasmodics

2 SMALL LUNGED EMPHYSEMA (ATROPHIC OR SENILE EMPHYSEMA)

Ætiology—This condition occurs in old age and forms part of the general atrophy of the tissues

Pathology—The alveolar walls become thinned and disappear so that adjacent alveoli coalesce The condition is primarily atrophic and therefore differs *from* true emphysema although the result is to produce a diminished area for aeration Post mortem the lungs are small and do not bulge or obscure the pericardium They are often deeply pigmented and are more spongy than normal but although bullæ occur they are small On section the lung tissue is bloodless and friable *The bronchi* may be slightly dilated and show catarrhal changes

Symptoms—These are slight and are masked by the enfeeblement due to the

septic processes such as otitis media and infective thrombo phlebitis Amœbic abscess occurs occasionally after dysentery and pulmonary abscess may be found as a rare complication of enteric fever (4) From infection of the lung tissue due to spread from adjacent disease This may occur in bronchiectasis in ulcerating new growths of the lung bronchi, œsophagus or mediastinal glands in caries of the vertebræ or ribs, and in suppurating mediastinal glands Rupture of an empyema, of a subphrenic abscess of a liver abscess or of infected hydatid cysts of the lung or liver may also lead to pulmonary suppuration Ten per cent of cases of abscess are due to new growths (5) As a sequel of perforating chest wounds or of fractured ribs piercing the lung

Pathology—Abscess of the lung is generally single and basic when consequent on pneumonia whereas embolic abscesses are often small and multiple and may be found in any part of the lung Abscesses due to extension from adjacent disease are generally solitary, and are often large and irregular The walls of acute abscesses are generally formed of congested and œdematous lung tissue, or of a zone of un resolved pneumonia Since acute abscesses commonly rupture quickly into a bronchus a fibrous capsule is unusual but in chronic abscess there is often considerable fibroid change in the neighbouring lung tissue The pleura may become involved over superficial abscesses leading to empyema or to pyo pneumothorax if rupture follows

Symptoms—Abscess may develop insidiously with comparatively slight symp toms More commonly they are an intensification of those due to the primary or antecedent condition The patient often appears seriously ill the fever becomes of septic type remittent or intermittent in character and of a high range Rigors and sweating are common Clubbed fingers are a characteristic and early sign The pulmonary symptoms at first may be only slight cough with scanty muco purulent expectoration Dyspnœa may be present and pain of acute character develops if the pleura is involved Hæmoptysis occurs in 70 per cent of cases of abscess A considerable leucocytosis up to 20 000 or 30 000 may be found and occasionally the breath may be offensive even before rupture into a bronchus occurs followed by the sudden expectoration of a large quantity of pus The pus is sometimes unpleasant or offensive smelling but has not the extreme fetor of gangrene Microscopical investigation will demonstrate the presence of pulmonary debris especially elastic tissue together with pus cells and micro-organisms After the expectoration of the pus the temperature usually falls and the general condition of the patient is much improved though cough and expectoration persist In chronic cases after rupture the temperature may become irregular and periodic a few days of normal temperature being followed by a period of fever and later by increased expectoration The physical signs in a deep seated or small abscess are often inconspicuous and comprise slight dullness over a small area weak breath sounds and possibly a few rales in the surround ing infiltrated or œdematous lung tissue With a large or a superficial abscess the signs before rupture may be those of consolidated or collapsed lung After evacuation occurs the characteristic signs of excavation usually develop at once In multiple embolic abscesses the signs are usually those of disseminated broncho pneumonia and in multiple abscesses due to staphylococcal infection widespread diffuse opacities may be apparent on radiographic examination These rapidly develop into cavities either empty or with a fluid level They may be mistaken for lung cysts owing to their thin walls

Complications and Sequelæ—The commonest complication is dry pleurisy This may progress to empyema or to pyo pneumothorax if rupture into the pleura occurs In some cases mediastinitis or pericarditis may develop Gangrene is de scribed but is a rare sequel Metastatic abscesses may be produced in other parts of the body especially in the brain and meningitis is a rare and serious complication The most important sequelæ are fibrosis of the lung with bronchiectasis pleural adhesion and rarely indurative mediastinitis

4 ACUTE VESICULAR EMPHYSEMA

Although custom has included this condition with emphysema, it is in reality *only a temporary* acute distension of the alveoli resulting from any condition causing widespread obstruction of the smaller bronchi It is sometimes observed after death in cases of acute bronchitis, whooping cough or asphyxia and in anaphylactic shock, and its existence may be inferred in severe asthma Post mortem the lungs are bulky and the alveoli distended

The symptoms are dependent upon the primary condition, although dyspnœa is invariably present The chest is found to be fully expanded, the vocal fremitus is diminished the percussion note is hyper resonant and the breath sounds vary with the condition inducing it In cases due to asthma the injection of a few minims of $\frac{1}{1000}$ adrenaline often produces visible deflation and helps to differentiate it from hypertrophic emphysema

5 ACUTE INTERSTITIAL EMPHYSEMA

In acute interstitial emphysema air is present in the stroma of the lungs and in the subpleural connective tissues It may follow external trauma such as fractured ribs, or wounds penetrating the lungs The alveoli may rupture with violent expiratory efforts as occur in whooping cough or influenzal broncho pneumonia It may occur in diphtheria The air sometimes tracks along the pulmonary roots to the mediastinum, and appearing in the neck or on the chest wall gives rise to surgical emphysema

Post mortem, subpleural bullæ may be seen containing air and on section of the lung minute air bubbles may be found in the inter alveolar connective tissue A diagnosis cannot be made unless the physical signs of surgical emphysema are present. The air is usually completely absorbed and a perfect recovery takes place No special treatment is required beyond keeping the patient at rest and giving sedative drugs to allay cough

ABSCESS OF THE LUNG

Definition —Abscess of the lung includes any circumscribed collection of pus ormed in the lung tissue but softened tuberculous areas and bronchiectatic accumulations are usually excluded

Ætiology —*Predisposing causes* —These include any diseases producing general cachexia or malnutrition notably diabetes and chronic alcoholism also any conditions leading to diminished resistance locally in the lung such as injury disease or exposure

Exciting causes —These are pyogenic organisms which reach the lung by inhalation by extension from adjacent suppurative processes or by the blood stream either directly or in septic emboli The common organisms found are streptococci staphylococci the pneumococcus, Friedlander s pneumo bacillus *Cl welchii* and *Bact coli*—sometimes acting in conjunction with putrefactive bacteria Spirochætes *F fusiformis* and other anaerobic organisms are often present especially after rupture has occurred Pulmonary abscess may form under the following conditions

(1) After inhalation of foreign material into a bronchus This may be a foreign body or may occur in association with septic conditions in the nose naso pharynx and larynx or during and after operations in these regions These are referred to as inhalation abscesses though some post-operative cases are regarded as due to embolism and not to inhalation (2) As a result of lobar or lobular pneumonia especially after the deglutition and aspiration varieties of the latter Such abscesses are sometimes called meta pneumonic (3) Embolic cau es—in pyæmia, or following on septic pulmonary emboli due to right sided septic endocarditis or derived from distant

In a considerable number of cases recovery takes place with penicillin and postural drainage alone

If in spite of postural drainage and the use of suitable antibiotics there is no steady progress of improvement from week to week surgical intervention is called for The operation of choice in these cases used to be external drainage after the sealing off of the pleura Resection however is more effective when the localisation of the abscess renders the procedure possible

Bronchoscopic drainage has its advocates and its successes but it has little advantage if any over postural drainage except that it is sometimes successful by making the patient cough Artificial pneumothorax is never advisable in these cases owing to the imminent danger of pyo pneumothorax

GANGRENE OF THE LUNG

In this condition localised or diffuse areas of lung tissue undergo putrefactive necrosis

Ætiology —*Predisposing causes* —These include old age over indulgence in alcohol general debility diabetes and insanity In certain rare cases especially after broncho pneumonia complicating measles gangrene of the lung is met with in children

Exciting causes and associated conditions —These are in the main identical with those of pulmonary abscess (see p 1002) In addition the pressure of aneurysm or of new growth on branches of the pulmonary artery may lead to gangrene The causal organisms are also very similar to those found in abscess of the lung and include staphylococci streptococci sarcinæ the *Micrococcus tetragenus Bact coli Ps pyocyanea F fusiformis* with its associated spirochæte and various anaerobes Some of these organisms yield putrefactive products with the liberation of phenol indole and skatole compounds

Pathology —It is not quite clear what are the factors determining whether abscess or gangrene occurs in an infected area of lung Doubtless the general resistance of the body the degree of local vascular disturbance and the virulence of the infecting organisms all play their part Laennec first described the two varieties of gangrene the circumscribed and the spreading or diffuse Around the former there are indications of a line of demarcation formed by congested lung tissue which may present the appearance of red hepatisation The surrounding lung tissue is invariably somewhat œdematous The gangrenous area is soft and pulpy and its colour varies from reddish brown to greenish black As the necrosis advances putrefactive liquefaction occurs with the formation of a horribly reeking fluid containing shreds and masses of necrotic lung tissue When this is discharged excavation results and isolated vessels may be seen running across the resulting cavity the walls of which are rough and covered with fetid pus The diffuse variety of gangrene is less common there is no attempt at a zone of demarcation and the whole of a lobe or of one lung may be affected In both forms the overlying pleura is intensely inflamed and empyema or pyo pneumothorax may be produced

Symptoms —These are similar to those occurring in abscess of the lung but are more acute The patient is desperately ill rigors are more common and sweating is more profuse The breath has a peculiar fetor which on account of the presence of the skatole group of putrefactive products in the gangrenous lung has an almost fæcal odour The sputum is intensely offensive and on standing separates into three layers similar to those of the expectoration in cases of bronchiectasis Elastic tissue is usually present Hæmoptysis is not infrequent and may prove fatal In rare cases gangrene is not accompanied by fetid expectoration especially when developing in the insane in young children and in diabetics or after pulmonary embolism

Diagnosis —This is difficult before rupture into a bronchus but abscess may be suspected from the gravity of the symptoms in relation to the history and signs especially if leucocytosis and fetor of the breath are present Radiographic examination may be helpful by demonstrating a localised shadow before rupture and excavation afterwards and also by establishing the situation of the abscess A fluid level can often be seen in films taken in the erect position although a fluid level may sometimes be more obvious if the patient is radiographed lying on one or other side or tilted to one side The sudden expectoration of pus followed by retrogression of symptoms and signs of excavation is very suggestive of abscess After rupture has occurred the differential diagnosis has to be considered from

1 *Interlobar empyema* —This may be very difficult or even impossible In this condition the signs are generally most marked in the region of an interlobar septum there may be some cardiac displacement, and the sputum, though purulent, does not contain elastic tissue

2 *Bronchiectasis* —The history the characteristic cough and sputum and the variation of the physical signs with the state of the cavity usually suffice to distinguish this condition A lipiodol or Neo Hydriol bronchogram will distinguish in doubtful cases since the oil does not as a rule, enter abscess cavities and the appearances in bronchiectasis are characteristic

3 *Gangrene of the lung* —This is a distinction with little difference except that gangrene is a suppuration of the lung that has not localised The extreme gravity of the patient s general condition and the horrible fetor of the breath and sputum are the most characteristic features of gangrene

4 *Tuberculous excavation* —The history, the distribution of the signs and the characters of the sputum including the presence of tubercle bacilli, are the distin guishing indications

5 *Purulent bronchitis* —The history the widespread physical signs and the absence of elastic tissue from the sputum usually serve to establish the diagnosis and lipiodol or Neo Hydriol investigations may be helpful

In multiple or pyæmic abscesses it is often impossible to recognise the condition though it may be suspected from the severity of the symptoms and signs In any doubtful case radiographic examination or tomography should be carried out if the condition of the patient permits The possibility of malignant growth as a cause of abscess should be borne in mind and when necessary bronchoscopy as well as lipiodol investigation carried out Exploratory puncture as a means of diagnosis is dangerous and should be avoided

Prognosis —The prognosis though grave in many cases is better than might be anticipated and has been much improved by modern treatment Pyæmic abscesses have a more serious prognosis except when staphylococcal which sometimes improved spontaneously even before the days of antibiotics

Treatment —Penicillin should be given in doses of 1 to 2 million units daily as soon as the diagnosis is made When sputum from the abscess is available the sensitivity of the various organisms should be tested in case any of them are penicillin resistant but are sensitive to streptomycin chloramphenicol, chlortetracycline or other antibiotics A careful record of the daily amount of sputum must be started and the patient given postural drainage in the position appropriate to the site of the abscess

The posturing must be kept up for as prolonged periods as possible Special beds on frames make prolonged postural drainage more effective and more comfort able Tapotage over the abscess in the correct postural position helps drainage of the abscess and breathing exercises should be combined with the postural drainage Once the abscess has started to discharge diminution in the measured amount of sputum should be accompanied by improvement in the clinical condition If it is not the drainage is imperfect Improvement must be correlated with radiological changes

of a bronchus and leading either to collapse or to bronchiectasis may if long continued cause fibrosis of the corresponding lung area Among such may be mentioned inhaled foreign body new growth cicatricial contraction and thoracic aneurysm

Pathology —The fibroid overgrowth may be (1) Massive or lobar (2) localised or insular (3) peri bronchial and (4) reticular

Any part of the connective tissue framework of the lungs and bronchi may contribute to the fibrosis In the massive form which generally affects the whole or the major part of a lobe or even of one lung the appearances in cases due to tuberculosis differ from those due to other causes In the tuberculous variety the primary distribution is usually apical and evidence of other tuberculous processes may be apparent in the form of large or small dried up cavities inspissated caseous material or calcareous masses enclosed in fibrous strands In non tuberculous processes the early localisation is commonly basal and although the primary cause may be obvious in the form of bronchial obstruction or some pleural condition this is not always the case On the other hand non tuberculous processes may involve the upper lobe primarily and fibroid tuberculosis may fall with special stress upon the lower lobe In both forms of fibrosis bronchiectasis may result although this is more common in the non tuberculous cases Apart from the special tuberculous lesions the end-results are very similar in both forms The affected area of the lung is shrunken and often devoid of air except for that in the bronchi and in the cavities It is dark in colour very firm and hard On section it presents a mottled appearance owing to the strands of blue grey fibrous tissue traversing it contrasting with the pigmented condensed airless lung tissue The fibroid area may be honeycombed by cavities or may present one large excavation due either to tuberculous cavitation or to bronchiectatic dilatation There is nearly always thickening and adhesion of the pleura The contraction of the abnormal fibrous tissue leads to marked displacement of the heart and mediastinum

The localised form is commonly due to healed tuberculous processes at an apex There may be simple puckering with or without pleural thickening and adhesion or a dense mass enclosing dried up caseous matter or calcareous spicules In bronchitic or broncho pneumonic processes a patchy fibrosis may occur described as insular fibrosis by Fowler

Reticular fibrosis is a rare condition in which the fibrous tissue in the interlobular septa seems to become increased as well as that around the bronchi It is at present only of pathological interest

Symptoms —The symptoms of pulmonary fibrosis are in the main expectoration and dyspnœa together with those of the primary affection In the non tuberculous cases bronchiectasis is so frequently associated that the symptoms and signs found are practically those of this condition Even in tuberculous cases some degree of bronchial dilatation is the rule although the sputum is rarely offensive The cough is generally periodic and associated with change of posture The expectoration is abundant and if bronchiectasis is present it has the usual characteristic features The dyspnœa is proportional to the extent of lung involved It may be extreme in the later stages when the heart becomes embarrassed and begins to fail Fever is usually absent except when complications occur

The patients are generally spare although nutrition may sometimes be well maintained until late They may show signs of deficient aeration in duskiness cyanosis and congested cheeks Polycythæmia sometimes occurs Clubbing of the fingers is almost constant Evidence of contraction is generally forthcoming in the flattening and retraction of the affected side with the dropped shoulder and compensatory spinal curvature Movement is greatly restricted contrasting with the increased expansion of the other side The cardiac impulse is sometimes much displaced especially in left sided cases when it may be in the left posterior axillary line or even under the angle of the scapula In right sided cases it is drawn to the right of the

The physical signs closely resemble those present in cases of pulmonary absce s and are those of consolidation before liquefaction occurs and of excavation afterwards The signs of the antecedent condition such as bronchiectasis aneurysm or malignant *disease may also be* present

Complications and Sequelæ—These are similar to *those met with in pul* monary abscess, but owing to the rapid course and greater fatality of gangrene they are not so common Cerebral abscess may occur

Diagnosis—The differential diagnosis is as for pulmonary abscess the dis tinguishing features being the extremely critical condition of the patient and the revolting fetor of the breath and expectoration Radiographic examination may give great assistance if the patient's condition permits it to be made

Course—The course is usually rapid, unless the diseased area is small and circumscribed In rare cases of localised gangrene of small extent, resolution and subsequent fibrosis occur

Prognosis—This is always *extremely grave, though a few cases of* localised gangrene recover spontaneously The prognosis is improved by early operation in suitable cases The outlook is said to be worse if the condition is apical, and diffuse gangrene is invariably fatal

Treatment—Operation is indicated when the general condition of the patient permits if the gangrenous area can be localised by physical signs or radiographic examination Exploratory puncture should not be carried out The other operative procedures are similar to those for abscess of the lung Operation is contraindicated in cases of diffuse gangrene The medical treatment is in all respects similar to that for pulmonary abscess Injections of neo arsphenamine, in doses of 0 3 g have given good results especially in cases due to fuso spirochætosis The sensitivity of the organisms in the sputum to the various antibiotics should be determined and the appropriate antibiotic given

PULMONARY FIBROSIS

Synonyms—Fibroid Disease of the Lung Chronic Interstitial Pneumonia Cirrhosis of the Lung

Definition—Pulmonary fibrosis is a late sequel of many acute and chronic inflammatory or irritative processes affecting the bronchi lungs and pleuræ It is therefore rather of pathological than of clinical interest and in no sense constitutes a separate disease, although the end results are remarkably similar in different forms *It is described here partly in deference to tradition and partly* to point out the methods of diagnosis between the various causes producing such strikingly similar effects

Ætiology—(1) The commonest cause is pulmonary tuberculosis particularly the fibroid and fibro caseous varieties (2) The group of pneumoconioses contributes a considerable number of cases *and possibly some varieties of* gas poisoning may induce fibroid changes (3) Broncho pneumonic processes particularly the forms associated with measles and whooping cough may be followed by widespread fibrosis especially in children (4) Although fibroid induration is commonly described as a sequel of lobar pneumonia *this disease is one of the rarer causes* (5) Localised fibrosis may occur around any circumscribed pulmonary or bronchial lesion such as that produced by syphilis leprosy glanders or actinomycosis Similarly it occurs about infarcts pulmonary abscesses and parasitic cysts (6) Chronic venous con gestion if prolonged leads to fibroid change which is referred to as brown indura tion This is usually of moderate degree and does not affect the clinical manifesta tions (7) Chronic pleural affections particularly those leading to adhesions or causing pulmonary collapse may induce fibroid changes within the lung and these forms are described as pleurogenous cirrhosis (8) *Any condition* causing obstruction

Nature of dusts —Dusts consist of particles or aggregates of particles suspended in air and measuring from 150 microns to 0 5 microns in diameter The sand of deserts the dust of streets and the pollens of plants are of such large particle size that they become trapped in the nose and upper respiratory passages and never reach the lungs Industrial dusts result from vigorous mechanical attrition blasting grinding drilling rubbing crushing hammering and sawing Particles 5 microns or less in diameter *can reach the alveoli of the lungs in the ashed lung specimens of men who have* died of silicosis the most representative particle measures 1 micron in diameter

Reaction of lung tissue to dusts —Of the dusts which do reach the alveoli silica and fibrous silicates set up different types of fibrous reaction in the lungs and the process is usually progressive But the dusts of some of the non fibrous silicates and of the compounds of certain metals among them calcium iron tin and barium seem to be inert when inhaled They are capable of lying in the lungs for years without inducing any deposition of fibrous tissue or other reaction but because they are relatively radio opaque they may produce changes in the X ray film which must then be distinguished from those of silicosis The resulting conditions are sometimes referred to as *benign pneumoconioses* The inhalation of vegetable and animal dusts may cause asthma and bronchitis indistinguishable from these diseases of non occupational origin

I SILICOSIS

Synonyms —Dust Consumption Ganister Disease Grinders Asthma Grinders Consumption Grinders Rot Grit Consumption Masons Disease Miners Asthma Miners Phthisis Potters Rot Rock Tuberculosis Stone Hewers Phthisis and Stonemasons Disease

Definition —A disease due to the inhalation of uncombined silica (silicon dioxide) Silicosis and pneumoconiosis must not be used as synonymous terms Logically one could classify the pneumoconioses as pneumoconiosis due to silica pneumo coniosis due to asbestos pneumoconiosis of coal miners and so on but such a method would be too cumbersome Legal considerations make it important that the term silicosis be reserved for that condition caused by the inhalation of uncombined silica the special characters of which render it capable of being identified when it occurs in typical form Dusts other than uncombined silica produce pneumoconioses but these do not present the characters which are possessed by silicosis in its typical form

Ætiology —The industries of sandstone quarrying mining and dressing are the most widespread of all silicosis producing industries in Great Britain In various parts of the world the granite industry the mining of gold hæmatite iron ore tin and coal sandblasting and the manufacture of refractory materials produce cases of silicosis The severity of the disease depends on such factors as duration and intensity of exposure dust particle size and to a large extent on individual susceptibility The *solubility theory* of its causation supposes that the fine particles of stone dust which get into the lungs are pathogenic not because they produce microscopic trauma but because a toxic substance dissolves from their surfaces This is thought to be silicic acid It has also been suggested that the role of silicic acid in silicotic tissue depends on its degree of polymerisation and that only highly polymerised silicic acids are capable of producing fibrosis

Pathology —Round nodules of fibrous tissue 2 to 5 mm in diameter are scattered throughout the lungs Several may be aggregated together to form large composite nodules or they may be united in a massive fibrosis Individual nodules may be thrown into sharp relief by emphysema of the surrounding lung and their centres sometimes undergo calcareous change Histologically the silicotic nodule is a mass of concentrically laminated dense fibrous tissue and similar changes are found in

sternum even sometimes under or outside the right nipple Vocal fremitus is either increased or diminished depending on the patency of the bronchus and percussion gives dullness of varying degree over the fibroid area, while the unaffected parts may be hyper resonant from compensatory' emphysema The diaphragm may be drawn up, and the liver or stomach correspondingly displaced The breath sound may be weak or inaudible but often when a deep breath is taken bronchial breathing can be heard especially if there is underlying bronchiectasis If there is cavitation the breathing will be cavernous or amphoric The presence of whispering pectoriloquy is an important indication that bronchial breathing will probably be heard Vocal resonance will be increased where the breath sounds are bronchial or diminished if the bronchi are not patent Adventitious sounds may be entirely absent and when present vary from rhonchi and bubbling râles to coarse metallic râles according to the presence or absence of excavation Radiographic examination gives useful confirmation showing contraction of the rib spaces scoliosis of the spine to the opposite side displacement of the trachea and heart to the side of the opacity in which translucent areas of cavitation may be seen occasionally

Diagnosis —The diagnosis is usually easy The evidence of contraction and of *mediastinal displacement towards the affected side especially if signs of cavitation* are also present is highly suggestive In the absence of the cavitation some difficulty may arise in regard to chronic pleural effusion or empyema In the earlier stages the contra lateral displacement of the cardiac impulse should prevent any mistake but where partial absorption has occurred, this may be very slight or absent In such cases an exploratory puncture or a radiographic examination may be helpful

When the diagnosis of pulmonary fibrosis has been made the differentiation of the cause is an essential to prognosis and treatment If the condition is apical there is a presumption in favour of tuberculosis if basal some other cause is more probable Repeated examinations of the sputum should be made for tubercle *bacilli* and if these prove negative radiographic examination may reveal some cause such as new growth aneurysm or even foreign body In some cases a careful consideration of the history may afford a clue to the diagnosis

Course —*The course is invariably chronic* and may not shorten the natural span of years

Prognosis and Treatment —These depend upon the primary condition but in most cases the latter is mainly symptomatic

G E BEAUMONT
E R BOLAND

THE PNEUMOCONIOSES

Definition —A group of lung diseases which result from the inhalation of dust in various trades Strictly they should be called *Pneumonokoniosis*

Classification —The pneumoconioses can be considered under headings according to the nature of the dust involved

1 Silica
2 Coal
3 Fibrous silicates
4 Non fibrous silicates
5 Non pathogenic inorganic dusts
6 Pathogenic inorganic dusts
7 Vegetable dusts
8 Animal dusts

exhaust ventilation must be used in such an occupation Where castings and other metal objects are cleaned by sandblasting the man wears a special dress so arranged that he breathes pure air from outside the sandblasting cabinet It is better to use shot blasting in which crushed ball bearings replace sand The steel powder resulting is harmless The hydro blast is the safest apparatus used to clean castings A high velocity jet of sand and water is projected on to castings thereby removing moulding material cores and scale The velocity of the water as it leaves the hydro blast gun is in excess of 3 miles per minute In all these trades where it is found impossible to control the dust completely the worker must wear either a dust mask or an air line breathing apparatus

Pre employment clinical and radiographic examinations of the chest are essential Periodical radiographic examinations enable silicosis to be detected at an early stage They therefore help to get men out of a dusty industry before damage to the lungs has gone too far They are also a means of discovering men with pulmonary tuberculosis who not only expose themselves to additional risk by remaining in the dusty occupation but are possible sources of infection to their fellow workers

2 PNEUMOCONIOSIS OF COAL MINERS

Synonyms—Pneumoconiosis of Coal Workers Coal Miners Asthma

Definition—A dust disease of coal workers slowly disabling and quite different from classical silicosis The rise in its incidence particularly in South Wales since 1925 can be related to the great increase in the amount of dust which has followed the mechanisation of the industry

Ætiology—The bulk of cases occurs in colliers working at the coal face and to a less extent among other underground workers That the disease is also found in surface workers on the screens and in coal trimmers at the docks strongly suggests that the causative agent is coal dust and not silica Classical silicosis occurs in only the small percentage of coal miners who are exposed to silica dust in the occupations of ripping brushing driving a hard heading and driving a cross measure drift but both coal pneumoconiosis and silicosis are often indistinguishably combined The highest incidence of the disease is found in the mining of high rank coal or anthracite it is less common in medium rank or steam coal mines and least common in low rank or bituminous coal mines

Pathology—Throughout the lungs coal dust collects in foci around the small bronchioles and their accompanying arteries and a diffuse network of reticulin fibres is laid down around these foci In certain cases the air spaces around the coal foci become dilated an appearance described as *focal emphysema* these emphysematous spaces may enlarge and become confluent although bullæ projecting from the surface of the lung do not occur In other cases a progressive coalescent collagenous fibrosis occurs leading to the formation of nodules and later to a massive fibrosis This fibrosis may be due to a sporadic factor such as silica with possibly a complicating tuberculosis infection In some cases the changes of tuberculosis predominate

Symptoms—The clinical course of the illness may cover many years and routine radiographic examinations usually show changes in the lungs before the onset of symptoms Dyspnœa and cough productive of coal black sputum are the most prominent the chest becomes emphysematous and there may be clubbing of the fingers The earliest radiographic change is a fine network of pinhead shadows sometimes sharp and lace like but much more often blurred Such shadows are variously known as *reticulation* or *pinhead mottling* They are followed by the stage of *nodulation* where the nodules are 2 to 5 mm in diameter The next stage is one of coalescent nodulation and in more advanced cases there are multiple less well defined fluffy shadows Large well defined dense massive shadows are seen in advanced cases of *progressive massive fibrosis* Focal emphysema cannot be diagnosed in life but its

the tracheo bronchial lymph glands Tuberculosis often complicates silicosis and the pathological appearances of the one may obscure those of the other

Symptoms—There is usually a history of exposure to silica dust of about 30 years duration but the latent interval is extremely variable, varying from 6 months to 60 years and the patient has on occasion left the industry for some years before beginning to complain

Silicosis is generally divided into first second and third stages, or slight moderate and severe degrees The first stage the so called simple silicosis supervenes in a workman who has been employed in an industrial process involving exposure to siliceous dusts for a period of many years The onset of symptoms is marked by dyspnœa on exertion slight at first and later increasing in severity Throughout the illness dyspnœa remains the most important symptom Slight cough may be present from the first It is usually unproductive or with scanty sputum The general condition of the patient is unimpaired Physical signs in the chest are slight. Diminished expansion is scarcely if at all present Dullness can rarely be demonstrated and in older subjects there may be areas of hyperresonance due to emphysema There is no alteration of the breath sounds and there are no added sounds In this early stage the radiograph shows the presence of discrete nodular shadows circular and at the most 2 mm in diameter They may be partially distributed throughout the films more widespread or even generalised but they remain discrete In this stage, impairment of working capacity may be slight or absent

In the second stage dyspnœa and cough become established and further physical signs appear There is diminished expansion of the chest patchy dullness sometimes with bronchial breath sounds and scattered rhonchi, especially at the bases The radiograph shows the whole of both lung fields occupied by shadows indicative of nodulation and there is some coalescence to form more or less dense opacities There is always some degree of impairment of working capacity In the third stage dyspnœa leads to total incapacity The radiographs indicate areas of massive consolidation Right heart hypertrophy and then failure may supervene Pulmonary tuberculosis may be present in any stage of silicosis It may alter the symptoms, physical signs radiographic appearances and the whole course of the disease It is the most frequent accompaniment of silicosis Since tuberculosis of the lungs may simulate silicosis in radiographs no diagnosis should ever be made exclusively on radiographic appearances

Treatment—Silicosis is a man made disease and should be prevented In mining operations ample dilution of the air in the mine with fresh air is the simplest method of reducing the dust concentration Various forms of ventilation are in use Drilling with pneumatic hammer drills is responsible for much dust but usually wet drilling can be employed The method used consists of hollow drill steels through which a continuous spray of water passes After shot firing a mist projector is used to allay dust It is really an atomiser using compressed air and spraying a mixture of water containing 0 5 per cent of castor oil In order to avoid the hazard of dust inhalation no man is allowed to return to the rock face until 8 hours after the blasting charges have been fired

In the grinding trades sandstone wheels should be abolished and replaced by wheels made of harmless synthetic abrasives such as carborundum (silicon carbide) and corundum (aluminium oxide) Where sandstone wheels are still used the operations of rodding and hacking as well as the actual grinding of metals must be carried out under a continuous stream of water which is drawn away from a trough at the base of the rotating grindstone

In foundries steel and other metals are poured in the molten state into sand moulds and it follows that the final castings are partly covered with sand and therefore can produce silica dust when treated with particular tools Fettling (steel dressing) implies the use of a compressed air chisel to clean up a casting Locally applied

The radiograph shows a diffuse ground glass or fine cobweb appearance, mainly at the lung bases It changes later into a fine punctate stippling and extends to involve the middle and upper zones although the extreme apices usually remain unaffected The interlobar pleura is thickened and there is a shaggy appearance to the heart outline

Prognosis—Fibrosis develops more rapidly than in the case of silicosis and death may occur within 5 years of the onset of symptoms The incidence of associated pulmonary tuberculosis although not as high as in silicosis is significant Bronchial carcinoma supervenes in more than 10 per cent of cases

Treatment—Treatment is symptomatic only In asbestos mining wet rock drilling is imperative In factories and textile mills the principle of locally applied exhaust ventilation must be enforced to prevent the escape of asbestos dust into the air of any room in which work is done Suppression of dust in the cleaning of carding machines is best ensured by the use of a revolving brush fitted with a cover and connected to a portable vacuum cleaner By the use of closed in machines handling should be reduced to a minimum Dust washes must be used where necessary In Great Britain legislation has been so effective in controlling the disease that with few exceptions cases now diagnosed have industrial histories going back before 1931

(b) TALCOSIS

Talc is a hydrated magnesium silicate It is used as a toilet powder as a dusting agent for rubber tyres and gloves in ceramics and in the manufacture of paper Talc pneumoconiosis has occurred mostly in the mining and milling industry Disability is less than might be suggested by the radiographic appearance of nodular shadows distributed diffusely over both lung fields There is however an increased susceptibility to pulmonary tuberculosis

(c) SILLIMANITE PNEUMOCONIOSIS

The sillimanite group of minerals are all aluminium silicates and are used in the manufacture of high grade refractories Radiographic and histological changes have been found in workers exposed to the dust although there is no disability

(d) SERICITE PNEUMOCONIOSIS

Sericite which is a fibrous variety of muscovite has without justification been suggested as a cause of pulmonary disease The fibre particles are too small to produce the sort of reaction which is found in asbestosis they are however often present in the lungs of miners with silicosis because of the association of sericite with quartz

4 NON FIBROUS SILICATES

The minerals in this group are complex aluminium silicates combined with potassium magnesium or iron When inhaled as dusts they cause no disability but are capable of producing the radiographic changes of pneumoconiosis

(a) MICA

Mica is transparent and heat resistant and is therefore used for the chimneys of oil lamps and for peep holes in furnaces and stoves Because of its high resistance

presence may be suspected when there is intense dyspnœa leading to death from respiratory or right heart failure Where the changes are those of massive fibrosis, progression is less rapid unless active pulmonary tuberculosis unresponsive to treatment, supervenes The course of pulmonary tuberculosis is generally modified by coal pneumoconiosis and often its presence cannot be identified confidently in life This is in contrast with the severe type of infection which occurs in patients with silicosis Thus in coal pneumoconiosis the miner is more breathless than ill and dies of *miners' asthma* whereas in silico tuberculosis he is ill as well as breathless and dies of *miners phthisis*

Treatment —As in the case of silicosis treatment is entirely symptomatic Young men with quite advanced simple pneumoconiosis are usually not seriously disabled whereas men with progressive massive fibrosis are much disabled and their disability increases both with age and with deterioration in radiographic appearances It has been shown that simple pneumoconiosis does not progress in the absence of further exposure to coal dust, whereas massive fibrosis is nearly always progressive whether or not dust exposure ceases This is a strong argument in favour of periodic radiographic examinations Measures directed towards dust suppression are wet cutting wet drilling water infusion of the coal face and hand spraying of the coal face before the coal is pulled down Adequate ventilation is of course essential in reducing dust concentration

3 FIBROUS SILICATES

The fibrous silicates include asbestos talc, sillimanite and sericite

(a) ASBESTOSIS

Ætiology —Asbestos is the name given to a series of minerals composed of the silicates of magnesium and iron crystallised in silky and fibrous form Canada produces 65 per cent of the world s asbestos It is mined both in open pits and by underground methods In Great Britain the main processes involved in the asbestos industry include the crushing and disintegration of the raw material carding and card cleaning and finally the spinning of the yarn and weaving of the cloth Besides being woven, asbestos is ground and mixed with cement and plastics to make insulating slabs and many other articles Asbestosis can follow employment in any of these processes but the risk is greatest in the crushing disintegrating carding and card cleaning processes where there is most dust It seems that the fibrosis is caused by mechanical irritation from the asbestos fibres during the movements of respiration and that this peculiarity is related to the flexibility of the fibres not possessed by other foreign bodies

Pathology —Large areas of the lung are tough owing to the presence of fibrous tissue emphysema although extensive is usually localised to the lower and apical parts of the lungs and there are many pleural adhesions On histological examination the alveolar walls are diffusely thickened there is generalised fibrosis and throughout the lung tissue are seen fibres of asbestos and asbestosis bodies

Symptoms —The average length of exposure before the onset of symptoms is 7 years Dyspnœa is the most conspicuous symptom and it may be out of proportion to the signs found in the chest There is often a non productive cough with pain between or under the shoulders and behind the sternum but hæmoptysis does not occur except in the presence of pulmonary tuberculosis Clubbing of the fingers is not uncommon examination of the chest shows limitation of respiratory excursion sometimes with medium crepitations of a metallic tone in both bases Asbestos bodies are found in the sputum These are golden yellow structures of beadlike form elongated and often with bulbous ends and varying in length from 20 to over 200 microns An asbestos fibre forms the central core in the body

(b) PNEUMOCONIOSIS IN BAUXITE SMELTERS (SHAVER S DISEASE)

Between 1941 and 1943 *aluminosis* occurred at Niagara in men exposed to fume in the manufacture of the abrasive corundum (Al_2O_3) a form of artificial emery They heated bauxite an ore containing 80 per cent Al_2O_3 and up to 7 per cent SiO_2, with iron and coke in the electric ore at 2000 C Some of the bin men furnace feeders and overhead crane men developed diffuse fibrosis of the lungs with emphysematous bullæ but without silicotic nodules There were 13 deaths from pneumothorax. One man had 8 pneumothoraces and he is the only man seriously affected who still lives Meanwhile tuberculosis has not developed in the lungs of the survivors

7 VEGETABLE DUSTS

Chronic lung disease sometimes results from the prolonged inhalation of the dusts of bagasse cotton derris flax flour gum arabic grain hay hemp jute linseed malt, nuts paprika sisal straw, tea and wood It usually takes the form of chronic bronchitis indistinguishable from non occupational bronchitis and it is not accompanied by any characteristic radiographic appearance

(a) COTTON

Four conditions affecting the respiratory system are described in workers exposed to cotton dust in different parts of the world These are mill fever byssinosis weavers cough and an acute illness occurring among people who handle low grade stained cotton

(1) *Mill Fever* —Almost all workers suffer from *mill fever* or *cotton cold* when they begin to work in the cotton mills and a similar illness occurs on first exposure to the dusts of flax grain and malt Tolerance is established usually within a few days though symptoms may reappear following an absence from work for a time as short as 2 to 4 weeks Mill fever begins within 12 hours of exposure to the dust The temperature may rise as high as 103 F but returns to normal over night Headache malaise and exhaustion accompany the fever and occasionally nose bleeding nausea and vomiting occur Symptoms may reappear each night for the first few days or even weeks of exposure but most workers become acclimatised within the first month

(2) *Byssinosis* —

Synonyms —Strippers Asthma Grinders Asthma Cotton Card Room Asthma

Ætiology —The illness begins suddenly after many years of exposure to dust in the cleaning and carding of cotton especially in men who strip and grind the carding machines

Symptoms —Three stages are recognised in its development In the first stage the worker complains of an irritating cough with tightness in the chest and breathlessness usually on Monday hence the name *Monday fever* and he remains well for the rest of the week. In the second stage the symptoms extend over more days in the week and finally become permanent In the third stage the byssinosis is disabling tightness of the chest and dyspnœa due to chronic bronchitis and emphysema are so distressing that the worker has to leave the cotton industry

Treatment —The condition is reversible only in the early stages and for recovery to take place there must be complete withdrawal from exposure to cotton dust The treatment of chronic bronchitis and emphysema is discussed on p 1000

(3) *Weavers cough* —This is an acute illness confined to workers employed in cotton weaving sheds Outbreaks have always been associated with the handling of mildewed yarn which suggests that the causal agent is a fungus Tightness of the chest retrosternal pain dyspnœa and cough productive of purulent sputum are the

to the passage of electricity it is one of the essential minerals in the electrical industry Radiographs of workers exposed to mica dust have shown diffuse shadows in the *middle zones of the lungs sometimes with fibrosis of the peribronchial type*

(*b*) FULLER S EARTH

Fuller s Earth is an absorbent of grease and is used for the filtration of mineral oils, and as an ingredient of soap, wall papers and toilet requisites Fine punctate mottling with some co alescence has been described in the radiographs of men exposed to the dust The necropsy appearance is that of a soft patchy pneumoconiosis unlike the hard nodular appearance of silicosis

(*c*) KAOLIN

Kaolin or china clay is used in the manufacture of paper in ceramics as a filler in the rubber industry for paints for wall plasters and white Portland cement Extremely fine mottling or reticulation has been described in the radiographs of a *number of workers exposed to the dust*

5 NON PATHOGENIC INORGANIC DUSTS

The dusts of the salts of calcium, iron tin and barium are inert when inhaled and give rise to the *benign pneumoconioses* (see p 1009) Particles small enough to *enter the alveoli are engulfed in phagocytes which are either coughed up or deposited* in the aggregations of lymphoid tissue at the bifurcations of the bronchioles Radio graphic shadows may be produced the density of which varies directly with the *atomic weight of the element in the compound concerned Calcium (atomic weight* 40) inhaled as the dust of limestone marble lime or cement may give rise to non progressive arborescent shadows Iron (atomic weight 56) can cause reticulation or nodulation The radiographic appearances in the chest of an electric arc welder may be identical with those of silicosis but *welders siderosis* can be distinguished from silicosis by the complete absence of disability *Stannosis* a condition which results from the inhalation of salts of tin (atomic weight 118) gives rise to scattered dense punctate shadows with no associated symptoms or abnormal physical signs In *baritosis* or barium pneumoconiosis (atomic weight 137) there is no disability, but in radiographs there are small sharply circumscribed nodules evenly distributed throughout the lung fields

6 *PATHOGENIC INORGANIC DUSTS*

Aluminium is capable of producing fibrotic pulmonary lesions and manganese cadmium and vanadium give rise to chemical pneumonitis Both types of reaction can follow the inhalation of beryllium and its compounds (see p 385)

(*a*) ALUMINOSIS

Exposure to the inhalation of aluminium dust in Germany during the War of 1939–1945 gave rise to a condition known as *aluminosis* or *aluminium lung* The development of the illness was rapid and appeared to bear no relation to the length of exposure to the dust A dry cough with pain on breathing shortness of breath anorexia and gnawing abdominal pain were the main symptoms Radiographs showed focal shadows in the apices with a reticular appearance in the upper and middle zones later becoming confluent Spontaneous pneumothorax occurred in a few of the cases

8 ANIMAL DUSTS

The dusts of leather silk wool fur hair, bone horn and ivory are of minor importance in the causation of respiratory disease On the other hand the danders of cat, dog and horse, and the feathers of birds may be responsible for asthma Animal dusts sometimes carry infections especially anthrax (see p 79)

DONALD HUNTER

PULMONARY TUBERCULOSIS

Synonyms —Phthisis Consumption

Pulmonary tuberculosis embraces all the abnormal conditions induced by infection *of the lungs pleuræ and bronchial glands with the tubercle bacillus*

Ætiology —Predisposing Causes —*Age* —The maximum age incidence is between the fifteenth and forty fifth years although the disease may be encountered at any age Senile tuberculosis is more common than is generally recognised

Sex —The disease is more frequent in males but between the ages of 5 and 15 the female sex shows a preponderance

Heredity —Pulmonary tuberculosis certainly occurs with undue frequency in certain families Since the direct transmission of the tubercle bacillus to the infant is extremely rare two explanations seem possible—(1) Children born of tuberculous stock may inherit an increased susceptibility or diminished resistance the tuberculous diathesis or (2) they may contract tuberculosis on account of their exposure to massive infection in early life

Race —Native races suffer severely when first exposed In Europe people from isolated rural areas who migrate to cities are particularly susceptible with a high mortality and a high morbidity long urbanised races like the Jews are said to be relatively resistant

Occupation —The highest mortality from tuberculosis occurs in England amongst the workers in dusty occupations and conditions leading to overwork or to under feeding increase the liability to the disease

Environment —Overcrowding defective sanitation dampness dirt lack of sun light and insufficient ventilation are most potent factors in the spread of the disease causing both lowering of the resistance and increased facilities for direct infection

Trauma —Trauma involving the chest wall may be followed by active pulmonary tuberculosis *This is probably because the injury leads to activity of previously* arrested disease rather than to fresh infection at a spot of lowered resistance

Psychological —Psychical factors such as sudden mental shock grief or dis appointment may influence the outcome

The influence of other diseases and conditions —The following diseases predispose to the development of pulmonary tuberculosis measles especially when complicated by broncho pneumonia whooping cough influenza pneumoconiosis alcoholism diabetes syphilis congenital heart disease and insanity Tuberculosis may manifest itself for the first time during prolonged lactation or after repeated pregnancies when previously existent it often remains quiescent during pregnancy but it may spread rapidly after childbirth Contrary to the usual belief pulmonary tuberculosis not infrequently coexists with mitral stenosis Cases apparently following pneumonia *pleurisy or bronchitis are usually tuberculous from the onset*

EXCITING CAUSES —The causal organism is the *Mycobacterium tuberculosis* dis covered by Koch in 1882 It exists in four main forms human bovine avian and reptilian only the two former usually occur in man but avian infection has been recorded The human type is found in over 97 per cent of pulmonary tuberculous lesions though a higher proportion of the bovine type has been found in Scotland In glandular tuberculosis up to the age of 5 years over 80 per cent of the bacilli

main symptoms malaise, fever, frontal headache and aching pains in the limbs and back may also be present

(4) *Acute respiratory illness from contaminated cotton*—Contamination of cotton with *Aerobacter cloacæ* has been responsible for epidemics of an acute febrile condition in workers exposed to its dust Symptoms begin within the first 6 hours of exposure and include anorexia headache, vomiting cramp like abdominal pain and sometimes rigors The illness usually persists for 2 to 5 days

(*b*) FARMERS' LUNG

This condition follows the inhalation of the dust of mouldy hay or grain and fungus infection is probably a factor in its ætiology although its exact role has not been determined Cowmen and members of mobile threshing teams are especially at risk The clinical picture is that of chronic bronchitis and emphysema, which becomes progressively more severe with continued exposure Radiographs in the early stages show a fine alveolar mottling with evidence of compensatory emphysema In the later stages there is an increase in the density of the mottling and patches of opacity due to coalescent areas of fibrosis appear, with increase in the hilar and peri hilar shadows The patient must be removed from dusty work and treated with potassium iodide The prognosis is good

(*c*) BAGASSOSIS

Bagasse is the cellulose fibre of sugar cane which remains after the sugar has been extracted It is used for making boarding for the interior decoration of buildings and for thermal insulation Exposure to the dust occurs when workers use a shredding machine to break up the bales of bagasse The dust may give rise to a self limited respiratory infection with acute bronchiolitis severe dyspnœa, cough productive of scanty sputum and sometimes hæmoptysis Radiographs show miliary shadows throughout the lung fields There is usually gradual improvement with recovery in 6 weeks Rarely impaired resolution occurs and may lead to pulmonary fibrosis with the radiographic appearance of thick bands of fibrous tissue traversing the lung fields and simulating cavities

(*d*) PAPRIKA

In Hungary and Yugoslavia along the Danube the fruits of the paprika plant when picked late in the season are often infected with the mould *Mucor stolonifer* The dried fruits are made into red pepper and inhalation of the spores and mycelia by the paprika splitters may give rise to acute bronchitis and later to fibrosis of the lungs and bronchiectasis The grinders and packers of the red pepper never suffer in this way

(*e*) WOOD

Bronchial asthma can be due to allergy to wood dusts in particular to those of the South African boxwood (*Gonioma kamassi*) mansonia wood (*Sterculiacea altissima*) and Western red cedar (*Thuja plicata*) Gum acacia is the allergen responsible for *printers asthma* which occurs in men exposed to a spray used in colour printing to offset one printed page from the next It can be eradicated by the substitution of dextrose for gum acacia in the spray fluid

results in the formation of a structureless cheesy mass Further changes may now occur either softening with the development of a cold abscess filled with tuberculous pus' or calcification with the subsequent formation of gritty masses known as pneumoliths

2 *Cavitation* —Cavities result from the liquefaction of caseous areas and the expectoration of the resulting debris They may be no larger than a pea or may occupy the whole of one or more lobes A recent cavity has an irregular outline with rough shaggy walls and a vascular line of demarcation It is often traversed by trabeculæ formed by bronchi and vessels which may be partly or completely obliterated, while sometimes the trabeculæ consist of condensed lung tissue which originally separated adjacent cavities In chronic cases the cavity is surrounded by fibrosed lung tissue forming a pseudo capsule and its interior becomes lined by a thin smooth false membrane Small aneurysms may be found arising either from vessels running in the walls or in the trabeculæ of the cavity the former being the more common In some cases where hæmoptysis has occurred rupture of such an aneurysm is the cause

3 *Fibrosis* —Reactive changes in the lung stroma lead to the formation of fibrous tissue This may occur early or after caseation has taken place

In the majority of deaths from all causes old tuberculous lesions are found post mortem near the apex of one lung These consist of small nodules of arrested disease with thickening and dimpling of the adjacent pleura

Dissemination in the Lungs —The disease may spread from the primary peribronchial deposit—(*a*) by direct infiltration (*b*) by the peri bronchial lymphatics and capillaries leading to a racemose appearance or to peri bronchial fibrosis (*c*) by the subpleural and interstitial lymphatics with localised miliary dissemination (*d*) by inhalation into a bronchus of tuberculous material which is then carried to other parts of the same or to the opposite lung—this not infrequently happens after hæmoptysis and in cavitation (*e*) by the blood vessels *e g* generalised miliary tuberculosis may result from erosion of a caseous tubercle into a vein

The pathology of the clinically distinguishable forms of pulmonary tuberculosis will now be described

1 Acute Miliary Tuberculosis —A primary caseous focus may be discovered at the apex of one lung in the bronchial glands or at some distant spot in the body Local erosion of a vein may be found accounting for the dissemination of the disease The lungs are usually studded with minute grey tubercles the smaller ones requiring a hand lens for their recognition In very acute cases death occurs before any secondary broncho pneumonic changes take place Miliary tuberculosis may develop as a terminal event in chronic fibro caseous or fibroid tuberculosis The tubercles are then found in large numbers around the old foci of disease but to a less extent in the more remote portions of the lung

2 Chronic Miliary Tuberculosis —Reports of cases of this condition were commoner before the recognition of sarcoidosis and many cases were probably erroneously diagnosed It is questionable whether real chronic miliary tuberculosis exists although even before the use of streptomycin there were great divergences in the rapidity of development of miliary cases and some might almost have been termed subacute although their fatal termination was the same

3 Acute Caseous Tuberculosis —Large areas of consolidation form rapidly, which differ histologically from the common chronic tuberculous broncho pneumonia in that the alveolar exudate is more definitely inflammatory and contains fibrin In the rare lobar cases the rapid caseation and the presence of tubercle bacilli show that the caseous pneumonia is a specific process Firm yellowish patches which may be confluent are seen usually scattered throughout both lungs The affected areas are airless and sink in water Softening is generally present in varying forms up to actual cavity formation which may be extensive involving even a whole lobe

isolated conform to the bovine variety In tuberculosis of bones and joints up to the same age 29 per cent of the cases are of bovine origin

The bacilli may gain access to the body by inhalation by alimentary ingestion through the tonsils through the skin or possibly, in rare instances by hereditary transmission It is probable that in the majority of cases of pulmonary tuberculosis in adults, the organisms are carried direct to the lungs in the inspired air, and Ghon showed that in children who had died of tuberculosis of the lungs, a primary focus was present in the lungs in 92 4 per cent Calmette and others have demonstrated that the bacilli may gain access to the bronchial glands from the alimentary tract through the thoracic duct, or from the tonsils through the cervical and mediastinal glands but this is now considered to be an exceptional path of infection Cases have been recorded in which primary cutaneous infections have been followed later by active pulmonary tuberculosis Direct intra uterine transmission of the tubercle bacillus if it occurs at all must be so rare that it is a factor of negligible importance

The incubation period of tuberculosis is uncertain owing to the difficulty of deter mining when infection takes place It is believed by many authorities that the majority of individuals in a semi rural or semi urban country like Great Britain are originally infected in infancy early childhood or youth by the inhalation of bacilli in infected spray droplets or dried dust, or else by ingestion of bovine or occasionally human bacilli The inhaled bacilli produce a lesion in the tissue known as a primary lesion which has special characteristics

The focal lesion is relatively slight but the reaction in the regional glands is much more obvious and characteristic Three possible things may happen as a result of the tuberculous lesion The lesion may disappear leaving little or no trace the focal lesion and the regional glands may become fibrous and then calcified as described by Ghon, or the focal lesion or the glands may break down and infection may spread locally or generally through the blood stream

What happens in an individual infection depends on the dose of infection the age and general condition of the infected person and possibly the degree of inherited resistance to tuberculous infection The earlier the age at which infection takes place, the more serious the result

Following infection acquired resistance develops to a greater or lesser extent and is probably permanent The acquired resistance modifies the effect of any subsequent infection so that in post primary tuberculosis there is a much more severe focal reaction than in the primary infection and little or no regional glandular reaction It has been held that reinfection does not take place but that all tuberculosis subsequent to the primary infection is a reactivation or a spread from the original focus just as tertiary gummata in syphilis are not evidence of reinfection but of spread from an original primary chancre This theory would tend to discount the danger of contact infection in later life but, in fact there is a great deal of evidence to show that re infection is the common cause of post primary tuberculosis

Pathology—The earliest lesion in the lung is the formation of tubercles whose structure is described in the general article on tuberculosis Whereas pulmonary primary lesions may appear anywhere in the lung post primary lesions for some reason not understood generally appear first at one or other apex Each lesion often appears radiologically as an area of localised opacity in the subclavicular area This lesion was described first of all by Assmann although the lesion he described was from 1 to 2 in in diameter and probably consists of a tuberculous lobular collapse When the lesions are small they are described as minimal lesions Both these lesions may and often do develop into progressive tuberculous infiltration

SECONDARY CHANGES—1 *Caseation*—The tubercle is avascular and owing to this and possibly also to the action of tubercle toxins coagulation necrosis and fatty degeneration frequently ensue This combined process is known as caseation and

(e) *Laryngeal*—Hoarseness or aphonia may be the first symptom but laryngeal tuberculosis is almost invariably secondary to pulmonary disease although the latter may have been unsuspected

(f) *Gastro intestinal*—Anorexia and flatulence often occur early When they are accompanied by slight loss of weight and pyrexia the possibility of pulmonary tuberculosis should be suspected

(g) *Pleural*—Dry pleurisy is a frequent manifestation of latent pulmonary tuberculosis When a serous effusion develops its tuberculous character can be determined by laboratory investigations Pneumothorax developing in a previously healthy individual is a rare but often serious clinical mode of onset

(h) *Pneumonic*— Galloping consumption often begins with pneumonic manifestations especially in the young

(i) *Associated with other diseases*—Tuberculosis may follow immediately on an attack of measles, influenza or whooping cough especially if complicated by broncho pneumonia In some cases it develops at a later period after the acute disease

(j) *Senile*—In old people an insidious onset is common The disease may be of bronchitic type and the signs are often masked by emphysema There may be little or no rise of temperature Sometimes pneumonic or broncho pneumonic tuberculosis of the type more familiar in infants is found Sometimes the differential diagnosis is from bronchial neoplasm

THE CHIEF SYMPTOMS of pulmonary tuberculosis are—

Cough—This varies considerably in different types of disease It may be very slight or absent in generalised miliary tuberculosis or in any form in the insane It is sometimes dry persistent and ineffective especially in miliary extension in the lungs from an old focus of disease in bronchial gland tuberculosis or in pleurisy When there is associated bronchitis or caseation the cough is usually accompanied by expectoration which if very tenacious may lead to retching or even to vomiting particularly in the morning In laryngeal tuberculosis the cough is husky and frequently painful

Expectoration—In early disease there is usually no sputum and in some cases more especially in the fibroid type widespread lesions may be present with practically no expectoration When caseation is in progress or when there is secondary infection with bronchitis the sputum may be abundant and amount to as much as 20 or more ounces in the 24 hours It may be clear or mucoid or thick tenacious muco pus If mucoid it often contains small particles the size of a pin s head or larger of yellow caseous material Nummular sputum may be met with in active caseous disease especially with excavation This consists of flat rounded masses of muco pus with a somewhat distant resemblance to coins In tuberculosis the sputum is usually inoffensive If bronchiectasis or gangrene occurs as a complication the expectoration becomes typically malodorous Pulmonary calculi or pneumoliths composed chiefly of calcium carbonate or phosphate are sometimes expectorated They vary in size from a pin s head to a pea are irregular in outline and sometimes branched being derived generally from the walls of a cavity Although the occurrence of these does not necessarily indicate fresh activity in the lungs yet such a possibility should always be suspected and a careful watch maintained on the temperature during the next few days In some cases larger pneumoliths as big as a cherry may be coughed up, and those are frequently derived from calcified tracheo bronchial glands They may give rise to alarming symptoms at once and be the forerunner of fresh activity in the lungs

Microscopical examination—The presence of tubercle bacilli in the sputum is the most decisive test of the existence of this disease The small yellowish caseous particles should be selected from the sputum and appropriately stained If no tubercle bacilli are found samples from the whole sputum of the 24 hours concentrated by the antiformin method can be examined Droplets collected on a laryngeal

4 FIBRO CASEOUS TUBERCULOSIS —This is the commonest variety of the disease the appearances of the lung vary with the relative preponderance of the caseous and fibrotic changes The early lesions are miliary or broncho pneumonic but areas of caseation in varying stages including cavitation, are almost always present The older lesions show considerable fibrosis the strands of sclerotic tissue being pigmented and glistening The earliest lesion is usually near the apex of the upper lobe at the back *more rarely a little lower and towards the front* From this focus disease may spread directly or through the lymphatic bronchial or the vascular system to adjacent or distant parts of the lung An open cavity from which infected sputum can overflow and pass or be aspirated through the bronchial tree to lower parts of either lung is to be regarded as particularly dangerous Pleural adhesions are usually present over the oldest lesions and in the interlobar fissures

5 FIBROID TUBERCULOSIS —Fibrosis may be localised around a small arrested lesion, or may spread throughout a lung in which caseation or excavation has occurred One lobe or the whole lung is then contracted and firm In the interstices of the fibrous tissue which is usually pigmented inspissated caseous material calcareous patches or cavities are seen The shrinkage may lead to bronchiectasis especially in the lower lobes The overlying pleura is much thickened and adherent and the mediastinum is drawn over towards the affected side The opposite lung or the sound portions of the fibrosed one, may show compensatory emphysema

The bronchial glands —The tracheo bronchial glands are affected in all forms of pulmonary tuberculosis In post primary disease the glandular lesions are insignificant as a rule whereas in primary disease, depending on the stage of the disease they show considerable enlargement caseation or fibrosis with deep pigmentation and calcification Occasionally in apical tuberculosis the cervical glands on the affected side are involved

The pleura —This too is almost constantly affected The commonest changes are an early dry pleurisy and a later thickening with adhesions which may completely unite the visceral with the parietal layers In acute disease or active spread the pleura may be studded with miliary tubercles leading to a large serous effusion

The post mortem appearances of the lesions situated in the other organs found as complications of pulmonary tuberculosis are described in the respective sections dealing with them and include tuberculous meningitis peritonitis enteritis genito urinary tuberculosis and osseous tuberculosis There is usually atrophy of the skeletal muscles sometimes lardaceous and fatty degeneration of the liver and hypoplasia with fatty degeneration of the heart

Symptoms —The symptoms fall into three groups (Pottenger)—(1) pulmonary such as catarrh expectoration hæmoptysis and pleurisy (2) reflex such as pain cough and laryngeal irritability (3) toxæmic including malaise tachycardia pyrexia and loss of weight

ONSET —The mode of onset is very variable but certain forms can be recognised

(*a*) *The diagnosis is made by a routine radiological examination* and the patient has no symptoms whatever This does not unfortunately mean that the lesion can be ignored it may be the golden moment for treatment

(*b*) *Insidious* —The early symptoms may be malaise anæmia amenorrhœa cardiac irritability progressive loss of weight and slight rise of temperature *generally towards* evening Cough and expectoration often appear only when the signs in the chest are quite apparent

(*c*) *Catarrhal* —Colds which appear to persist with fatigue and persistent cough should be regarded with suspicion

(*d*) *Hæmoptysis* —Hæmoptysis may first draw attention to the lungs It may be slight and is then due to early inflammation around the focus of infection If it is more marked it may afford dramatic *evidence of extensive* disease which had not been recognised previously or arise from an old unsuspected cavity

(*a*) In acute miliary tuberculosis it may be continuous or remittent and the typus inversus is not uncommon the morning temperature being higher than the evening This is generally regarded as a sign of grave prognosis

(*b*) In acute caseous tuberculosis the high temperature at the onset is continuous and the record resembles a pneumonic chart When caseation occurs it becomes hectic or intermittent with a daily swing of 4° or 5° F This is probably due to the action of tubercle toxins and not to the presence of a secondary infection

(*c*) In chronic fibro caseous tuberculosis there is no characteristic temperature record There may be only a very slight rise occurring at intervals of a few days On the other hand the patient may be afebrile while resting but febrile when ambulant Further an afebrile ambulant patient may over exert himself and develop a sharp rise of temperature which subsides in a few days with rest The temperature chart is thus a guide to prognosis and to treatment and if acute miliary tuberculosis or caseation occurs a typical temperature variation ensues

(*d*) In fibroid tuberculosis the temperature is usually normal unless excessive auto inoculation results from exercise or the disease advances The occurrence of hæmoptysis may have a very definite effect upon the temperature In some cases it is not followed by pyrexia but if the inhaled blood leads to a hæmoptoic bronchitis there may be a slight degree of fever lasting for a few days When a definite and persistent pyrexia follows it usually indicates activity around an old focus of disease, or fresh spread by inhalation of blood containing tubercle bacilli to distant parts of the lung

A premenstrual rise of temperature may occur but as it is also met with in healthy women it is not pathognomonic.

Hæmoptysis—Hæmoptysis occurs at some stage of pulmonary tuberculosis in about 50 per cent of all cases With early lesions the sputum is only streaked This may result from the inflammation of tuberculous bronchitis or from a small area of collapse or broncho pneumonia Profuse hæmoptysis generally occurs in chronic disease but it is occasionally met with in acute caseous forms Recovery may take place after coughing up 2 or 3 pints or death may ensue rapidly from suffocation before any considerable quantity of blood has been expectorated After the cessation of bleeding the sputum may be blood stained for several days the colour becoming darker The source of profuse hæmoptysis is generally an aneurysm of a branch of the pulmonary artery lying in a cavity or in a fibroid lung although occasionally ulceration without previous aneurysm formation may occur In the majority of cases hæmoptysis begins while the patient is lying down or resting so that exercise or work are not frequent exciting causes

The patient notices a salt taste feels a warm gush in the mouth and then expectorates the blood He is usually greatly alarmed flushed and sweating with rapidly beating heart The blood at first is as a rule bright and frothy but some clots may be present later it is mixed with muco purulent expectoration in the form of clots or streaks

Circulatory system—The heart may be small but the right side often hypertrophies in chronic fibroid cases Tachycardia may be due to nervousness but when constant it generally indicates active disease or over exertion on the part of the patient The blood pressure is usually low in the stages of activity and a steady rise during treatment is a favourable sign

The blood—The red cells are usually normal in number but there may be a slight anæmia On the other hand when there is much cyanosis or after sanatorium treatment the red cells may be increased In the early stages the leucocytes may be slightly increased A polymorphonuclear leucocytosis occurs in caseation and in early cavity formation and at times with secondary infection of the lungs In pyrexial cases the sedimentation rate is raised as a rule Although the rate is raised in active disease a normal level cannot unfortunately be regarded as evidence of arrested

mirror by cough induced by it may be examined for the presence of tubercle bacilli, especially in children or in patients who habitually swallow sputum In similar cases, tubercle bacilli may be found by gastric lavage

Sputum culture by the Loewenstein or Dubos method may be of value when tubercle bacilli are not found in smears The cells present are usually of the mono nuclear type either mononuclear leucocytes or altered alveolar epithelial cells The presence of elastic tissue indicates that destructive pulmonary lesions are in progress Secondary infecting organisms may be demonstrated by cultural methods Failure to find tubercle bacilli in the sputum does not in any way exclude pulmonary tuber culosis since their detection depends on chance and diligence as well as on the stage of the disease Persistently negative sputum in patients with large quantities of purulent sputum should, however, suggest the possibility of alternative infections

Dyspnœa —Slight dyspnœa occurring early in the disease may be due to dimin ished movement of the diaphragm on the affected side In more advanced cases the degree of dyspnœa is proportional to the amount of lung tissue involved In addition, cough and pyrexia play a part in its production Complications such as pleurisy pleural effusion pneumothorax and cardiac failure increase the shortness of breath It is rare to find orthopnœa even in acute and rapidly spreading disease In arrested cases the dyspnœa is proportional to the extent of fibrosis

Cyanosis —This is not an early symptom of tuberculosis It is dependent upon the amount of lung tissue involved but is increased by the coexistence of emphysema or cardiac failure The ' hectic flush ' of tuberculosis is a vasomotor effect caused by toxæmia

Pain —Not every sufferer from tuberculosis experiences pain even in the acute stages of the disease The commonest cause of pain is dry pleurisy When the diaphragmatic layer of the pleura is affected, pain may be referred to the epigastrium or to the corresponding shoulder In chronic fibroid phthisis there is frequently a dull, aching pain in the chest It may be caused by the contraction of the condensing fibrous tissue Cutaneous tenderness of the chest wall is met with in some cases of advanced disease, and is probably due to a cachectic neuritis A cold abscess forming along one of the ribs or costal cartilages is a rare cause of localised pain in the chest-wall Cough may be painful especially when paroxysmal or frequent the pain being referred to the costal attachments of the diaphragm and upper abdominal muscles The sudden occurrence of pneumothorax may cause such severe pain as to induce collapse, but when of more gradual onset no severe discomfort may be experienced Tuberculous laryngitis may be the cause of very great suffering

Night sweats —Although not pathognomonic night sweats occur more frequently in tuberculosis than in other diseases They are met with in all stages of active lesions, and may be of great severity

Loss of weight —This is often an early symptom It is most marked in acute disease and in the late stages of chronic fibro caseous tuberculosis

Fever —Pyrexia is one of the most important indications of activity at any stage of pulmonary tuberculosis although it does not follow that the disease is arrested when there is no fever During treatment the temperature should be recorded at certain definite hours in the day (*a*) On waking The normal mouth temperature at 7 or 8 a m is 97° or 98 F in the mouth and 97 2° to 99° F in the rectum This temperature should be taken in bed before eating or drinking (*b*) At 1 p m , after the hour s recumbent rest (*c*) At 6 p m (*d*) At 9 p m after retiring to bed The maximum temperature is usually reached between 4 and 6 p m but may be delayed to 8 or 9 p m The temperature is dependent upon the extent and the activity of the disease and upon the amount of exercise taken Only 5 minute readings should be accepted

Adventitious sounds may be absent but usually fine or medium crackling râles are heard with inspiration especially after coughing When active softening is in progress the râles frequently become coarse and crackling The voice conduction is much increased bronchophony and whispering pectoriloquy being audible

THE PHYSICAL SIGNS OF EXCAVATION —Flattening of the chest wall and diminished movement over the cavity are now more marked if the cavity is apical there is in addition notable dropping of the shoulder and wasting of the shoulder girdle muscles

The diminution of movement is confirmed by palpation Vocal fremitus is generally increased owing to the surrounding consolidation but if the cavity is full or there is much pleural thickening it is diminished

The percussion note is dull when the cavity is small or filled with secretion A peculiar boxy or cracked pot' note the bruit de pot fele is obtained over large superficial cavities especially when communicating with an open bronchus This is best heard on percussing with the mouth open and Wintrich showed that the note may be altered in pitch over such cavities when percussing with the mouth open or closed apart from the actual presence of the cracked pot sound

The breath sounds are bronchial broncho cavernous cavernous or amphoric, according to the size of the cavity and to the amount of its contents When it is full the breath sounds may be distant weak or even absent and this is especially noticeable in basal bronchiectasis

With a dry cavity there may be no adventitious sounds Usually râles are audible they may be medium or large and bubbling or crackling in character Over a large cavity a metallic tinkle and amphoric echo may be heard With a very large cavity extending through the whole of one lung a typical *bruit d airain* is at times obtainable Voice conduction is increased bronchophony and whispering pectoriloquy are present and in some instances post tussive suction is heard Some cavities are only revealed by radiographic examination or by tomography

THE PHYSICAL SIGNS OF FIBROSIS —The chest is asymmetrical the affected side being flattened and moving little while compensatory scoliosis or kypho scoliosis is often present The cardiac impulse is seen to be displaced towards the affected lung and may be higher or lower than normal It may be drawn over to the right axilla or on the left side as far back as to the posterior axillary line or even to the angle of the scapula The intercostal spaces may be retracted and dilated venules are sometimes seen over the front of the chest as the result of obstruction caused by displacement of the mediastinum and traction on the deeper veins

Diminution of movement is confirmed by palpation and the cardiac impulse can be more accurately localised Vocal fremitus may be increased or diminished the former occurs when the lung is consolidated and the large bronchi patent the latter when there is much pleural thickening

The percussion note over fibroid lung is dull and the sense of resistance increased unless cavities are present The opposite lung may be hyper resonant and its resonance extend across the mid sternal line The cardiac dullness is often continuous with that of the fibroid lung and its area can only be determined by the cardiac pulsation

The breath sounds may be weak and distant or bronchial in character depending on the patency of the bronchi and the presence of cavities

Often there are no adventitious sounds although fine or medium rales of a sticky or metallic nature may be heard The voice conduction may be diminished or there is pectoriloquy and bronchophony

It must be borne in mind that in actual disease the lesions are not so clear cut and well defined In a case of some duration different stages of disease can be found in the same individual thus infiltration consolidation with softening excavation and fibrosis may be present in different lobes of the lungs and thus it may be possible to determine the site of origin and path of spread of the disease

disease as the initial rate is not infrequently normal in spite of progressive disease

Alimentary system —The tongue is usually clean and the appetite good even in cases with marked fever When tuberculosis of the larynx is present there is frequently severe dysphagia Dyspepsia may be complained of, anorexia flatulence and distension with nausea are the commonest symptoms pain being rarely noticed There may be marked intolerance of fat in the diet Atonic dilatation of the stomach may occur in some cases towards the end of the disease

Nervous system —The classical spes phthisica is rare, but when present is very striking by its contrast with the realities of the disease It should be remembered that the reality of the disease is known only to the physician and not the patient and it might be as reasonable to talk about spes carcinogenica' in a patient who has no idea that he has a growth Spes phthisica is sometimes a bold front put up by a patient and stands in sharp contrast with the depression and melancholia which often affects patients whose lesions are slipping Patients with chronic tuberculosis sometimes become emotional and self centred but most of the psychological changes are the result of the long periods of treatment and frequent disappointments characteristic of the disease and are not caused by the disease itself Insomnia may be due to cough pyrexia night sweats or pain, especially laryngitis With marked cachexia a definite peripheral neuritis may occur

Genito urinary system —In the early stages there is often an increased sexual desire and this may recur when arrest is taking place This is probably in part due to the therapeutic regime, the rest abundant food and lack of interesting occupation reacting upon the nervous system of young adults In advanced disease all sexual desire is lost Menstruation ceases early and occasionally the patient may seek advice for amenorrhœa but this occurs more often in acute or advanced cases Women remain fertile even in advanced disease The urine is normal in the early stages, later a febrile albuminuria may occur or in advanced cases an amyloid nephrosis with generalised œdema may develop

THE PHYSICAL SIGNS OF EARLY DISEASE —*There are no physical signs in really* early disease and the diagnosis is a radiological one At a later stage diminished expansion of an apex may be found together with slight impairment of percussion note and slight increase of breath sounds and voice conduction An important physical sign is the presence of fine post tussive crepitations at one or both apices *Many of the physical signs described in previous days as signs of early tuberculosis* although they can be found by the skilled examiner are now really only of historical interest and none replace a radiological picture in accurate diagnosis

PHYSICAL SIGNS OF ACUTE MILIARY TUBERCULOSIS —If the condition develops acutely from breaking down of an infected bronchial gland or small lung focus the physical signs are generally those of an acute generalised broncho pneumonia unless there is meningeal involvement as well in which case the pulmonary symptoms and signs are masked or obscured by those of the cerebral involvement When miliary tuberculosis occurs as a terminal event in a chronic case marked dyspnœa cyanosis and tachycardia are early symptoms There may be crepitations or fine crepitant râles widely distributed over both lungs and sometimes areas of tubular breath sounds especially in the lower lobes The original signs are often masked or less apparent This is especially the case if meningeal involvement occurs also

THE PHYSICAL SIGNS OF CONSOLIDATION —Limitation of movement and flattening over the affected part of the lung usually the apex is now more noticeable

The diminution of movement is confirmed on palpation and vocal fremitus is found to be *definitely increased*

The pulmonary resonance is diminished to definite dullness and the sense of resistance is correspondingly increased

The breath-sounds are bronchial

Fatty degeneration of the myocardium occurs as a result of toxæmia and infection by direct spread along the lymphatics may lead to pericarditis The peripheral circulation is not infrequently poor, chilblains are common and cachectic purpura may be seen Lardaceous degeneration as a consequence of chronic tuberculosis is not so common nowadays as formerly but when present may affect the liver spleen intestines lymph glands and kidneys

The genito urinary complications include lesions in the kidneys bladder epididymis and prostate If the suprarenal body is affected Addison's disease will usually develop Spinal caries is occasionally observed A peripheral neuritis may form part of the lesions occurring with marked cachexia Generalised dissemination of the tubercle bacilli by the blood-stream is followed by tuberculous meningitis

Diagnosis —This is easy when definite signs are present in the lungs and when tubercle bacilli are found in the sputum On the other hand the diagnosis of early cases may present one of the most difficult problems in clinical medicine Tuberculosis may be suspected on account of symptoms although the physical signs are indefinite The conditions which most frequently lead to doubt are dyspepsia neurasthenia debility tachycardia associated with early Graves disease or heart disorders affections of the nose and throat and in children enlargement of the bronchial glands The history and symptoms are of great importance in these cases and a careful examination should be made of each system A test meal opaque meal or blood examination may be required before the correct diagnosis is established

On the other hand there may be definite signs of disease in the lungs which have to be differentiated from those produced by other conditions simulating tuberculosis The cases included in this group embrace the majority of pulmonary lesions especially chronic bronchitis fibrosis bronchiectasis asthma, emphysema apical collapse pleurisy new growths and cysts Diagnosis depends upon the history and course of the disease together with a careful record of the physical signs in the chest, investigation of the sputum for infecting organisms radiographic examination and in some cases the determination of the Wassermann reaction

A condition of special difficulty is that of the variety of sarcoidosis known as Boeck s sarcoid The lesion is a benign lymphogranuloma or reticulosis It affects the lymph glands lungs bones especially those of the fingers and the skin (see pp 1045 1245) The parotid and lachrymal glands are sometimes involved and iridocyclitis has been recorded in 10 per cent of the cases The intestines spleen and liver may be affected The chief diagnostic points are the character of the skin lesions and the chronicity and tendency to spontaneous arrest Tubercle bacilli are not found and the Mantoux reaction is often negative The radiological appearances in the lungs are those of a diffuse mottling—coarser than that of miliary tuberculosis The hilar glands are often markedly enlarged

When the diagnosis still remains doubtful the patient should be placed under observation and a series of examinations carried out the object of which is to determine whether or not active tuberculosis is present The temperature should be observed with the patient in bed a daily rise to 99 F or a swing of 1 5 to 2 below normal being suspicious The sputum should be examined repeatedly for tubercle bacilli by the ordinary method and if not found the antiformin process should be carried out and gastric washings should be examined and cultivated

The sedimentation rate of the erythrocytes is affected in this disease In active cases the sedimentation rate is increased but this reaction is not specific It is also increased in other conditions such as pregnancy carcinoma syphilis rheumatism and acute infections The test is therefore of little or no value in diagnosis but it affords valuable indications of the degree of activity and may assist in determining the form of treatment A normal sedimentation rate unfortunately does not necessarily mean that the tuberculous disease is quiescent As in radiology it is often the serial records that are most valuable

Certain other signs are occasionally seen in pulmonary tuberculosis

Myoidema is an undue irritability of the muscles to direct mechanical stimulation revealing itself by a flickering fibrillary contraction on tapping with the finger, and may occur in tuberculosis at all stages It is best seen over the pectoralis major on the affected side It may be present quite early, but is not pathognomonic, as it may occur in any cachectic state

Clubbing of the fingers is commonly seen in chronic cases, the nails are curved and present a parrot beak appearance, the thumb index and middle fingers being most affected Drum stick clubbing is only seen in fibroid lesions with bronchiectasis

EPITUBERCULOSIS —This term was applied by Eliasberg and Neuland in 1920 to a condition of consolidation in tuberculous infants, often affecting a whole lobe In spite of definite physical signs and characteristic radiological appearances there are few symptoms and recovery is the rule with fairly rapid clearing of the radiographic shadows from the periphery inwards It is probably due to atelectasis of a lobe in whole or part due to bronchial obstruction from enlarged hilar glands

PULMONARY OSTEO ARTHROPATHY —In cases with bronchiectasis the joints may be affected, swelling occurring especially in the wrists, ankles and knees and rarely in the hips and shoulders A serous effusion into the joints may be present Pain is usually slight but there is much deformity and functional impairment Radiographic examination reveals productive periosteal changes which may also affect the long bones and the spine (see p 1171)

RADIOGRAPHY OF THE CHEST —Careful study of serial radiographs is essential for the control of the treatment and progress of pulmonary tuberculosis Examination of the chest with the fluorescent screen gives valuable information as to the movements of the diaphragm the cardiac pulsation and the lighting up of the apex of the lungs with inspiration Tomograms often show unsuspected cavities in the lung and are also valuable to show the extent of pulmonary infiltration Close studies of serial pictures are necessary to determine the activity or otherwise of the radiological lesions Opinions as to the activity of lesions on the basis of hardness or softness of the shadows are of little or no value

Complications and Sequelæ —Compensatory emphysema is common in chronic fibroid disease but bronchiectasis occurs less frequently Gangrene of the lung is not often observed Colds and catarrhal affections of the respiratory passages are frequent in sufferers from tuberculosis, and lobar pneumonia may develop as a complication Bronchitis often occurs due either to spread of the tuberculous process or to a secondary infection In some instances asthma appears for the first time after tuberculosis has become manifest A tuberculous abscess occasionally forms about a rib or costal cartilage

Small areas of dry pleurisy are present at some stage in nearly every case a serous pleural effusion is common and an empyema may develop as the result of a mixed infection, or from the tubercle bacillus alone Pneumothorax may occur as an early complication or late in the disease generally from rupture of a caseous focus just under the pleura, this frequently progresses to the formation of a pyo pneumothorax The implantation of tubercle bacilli from the expired air or sputum may lead to secondary foci in the larynx, trachea and epiglottis, or more rarely in the pharynx, tonsils base of the tongue or nose Swallowing of sputum containing tubercle bacilli may give rise to gastro intestinal complications in some cases The most common site of tuberculous ulcers is the terminal portion of the small intestine but the appendix may be affected and the connective tissue around the cæcum is sometimes matted and thickened to form a palpable mass (hypertrophic tuberculoma) Tuberculous peritonitis is not common in adults and is usually secondary to intestinal lesions The stomach is very rarely ulcerated but an atrophic gastritis may occur in advanced cases Fistula in ano and ischio rectal abscess are comparatively common complications and tubercle bacilli may be found in the discharges

e g there should not be marked acceleration of pulse or elevation of temperature except of very transient duration gastro intestinal disturbance or emaciation if present should not be excessive Obvious physical signs and radiological findings should be of very limited extent The physical signs should be either present in one lobe only and in the case of an apical lesion of one upper lobe not extending below the second rib in front or not exceeding an equivalent area in any one lobe or where these physical signs are present in more than one lobe they should be limited to the apices of the upper lobes and should not extend below the clavicle and the spine of the scapula Radiological findings should be limited to mottling involving a total area of not more than one zone No complications (tuberculous or other) of *prognostic gravity should be present A small area of dry pleurisy should not exclude* a case from this Group

Group 2—All cases which cannot be placed in Groups 1 and 3

Group 3—Cases with profound systemic disturbance or constitutional deterioration and with marked impairment of function either local or general All cases with grave complications whether they are tuberculous or not should be classified in this Group (*e g* diabetes tuberculosis of intestine or larynx)

Apart from the question of the expectation of life various stages of tuberculosis are described based upon anatomical lesions toxæmia and functional disablement

The course taken by tuberculosis of the lung may lead to several terminations These are (1) permanent arrest either by fibrosis prior to caseation or if the latter has occurred by calcification and fibrosis (2) incomplete arrest as shown by the persistence of tubercle bacilli in the sputum or by slight degrees of pyrexia on over exertion (3) rapid extension here the disease spreads and the toxæmia is out of all proportion to the extent of the lesions (4) death this may result from the pulmonary lesion or from complications The lesion may prove fatal as the result of progressive asthenia or cardiac failure from asphyxia due to acute miliary tuberculosis or hæmoptysis or in a small proportion of cases directly from loss of blood in repeated hæmoptysis The complications that most often prove fatal are meningitis enteritis laryngitis leading to dysphagia and starvation or pneumothorax Intercurrent diseases such as pneumonia influenza or diabetes are occasionally the cause of death

Prognosis —A number of factors must be critically considered in the determination of the prognosis in pulmonary tuberculosis

Rapid progress of the disease in other members of the family suggests a diminished familial resistance and therefore an unfavourable prognosis

Personal history —Chronic alcoholism is serious chiefly because the regime of treatment is then peculiarly irksome while the digestion and powers of resistance are often impaired in alcoholics The outlook is grave when tuberculosis is conjoined with diabetes though less so since the use of insulin Congenital heart disease and pulmonary stenosis are unfavourable factors but hypertrophy of the heart and mitral stenosis are said to be beneficial

The prognosis is very grave in infants and young children but slightly less serious up to the age of 20 Between 20 and 50 age has little influence but in later years the outlook becomes progressively less favourable

Apart from the effects of pregnancy and exposure sex plays no important part

Freedom from financial embarrassment improves the prognosis inasmuch as advice can be sought early and treatment carried through thoroughly

Marriage often leads to a breakdown in arrested cases especially in women and induces more rapid spread of active lesions

Persistence in an unfavourable occupation or return to it after completion of institutional treatment affects the prognosis adversely

Poor chest development and the habitus phthisicus are usually bad prognostic signs although tuberculosis may run a rapid course even in patients with good physique

It has also been used as a guide to prognosis since it is affirmed that arrest should not be considered as firmly established until the sedimentation rate has returned to normal This may not occur until some time after the usually accepted clinical symptoms and signs of activity have disappeared

THE TUBERCULIN TESTS —1 *Cutaneous* (*the Pirquet reaction*) —Scarifications are made on the skin of the forearm through a drop of Koch s old tuberculin, human or bovine and through a drop of saline as a control A positive reaction is shown by the formation of a slightly raised, reddened papule at the site of the scarification through one or other varieties of tuberculin, whereas the control is not affected Unfortunately except in the first 2 years of life this affords no indication of active disease, but only reveals the presence of previous infection with resulting tuberculin sensitiveness A positive reaction is therefore given by the majority of adults

2 *Mantoux s intradermal test* —An injection of 0 1 ml of a 1 in 10,000 dilution of old tuberculin (0 01 mg) is given intradermally If no reaction occurs, the injec tion is repeated in a week with 0 1 ml of 1 in 1,000 dilution (0 1 mg) If still negative 0 1 ml of 1 in 100 dilution may be used A positive reaction is shown by a red areola with some œdema of at least 5 mm in mean diameter after 2 or 3 days

A modification of this test consists in the use of Purified Protein Derivative (P P D) This is supplied in tablets of two strengths which must be dissolved in a buffered solution immediately before use The advantage of this preparation is its constant potency

3 *Vollmer s patch test* —A strip of adhesive plaster is applied over the sternum previously cleaned with ether To this strip are attached three small squares of filter paper the central one is a control of untreated paper, the other two have been saturated with undiluted old tuberculin and allowed to dry The plaster is removed in 48 hours and 12 or 24 hours later a positive reaction is shown by redness infiltra tion and sometimes by papules or vesicles

4 *Tuberculin jelly patch test* —The jelly which contains 95 per cent old tuber culin is squeezed out from a tube on to the skin between the shoulder blades which has been cleaned with acetone It is covered before drying with Elastoplast which is removed 48 hours later A positive reaction is shown by erythema with slight vesiculation This test is more accurate than the Vollmer test and gives as high a percentage of positives as does the Mantoux test

Course —The course pursued by pulmonary tuberculosis is variable depending upon the type of the disease In acute miliary tuberculosis before the use of strepto mycin, death could occur within a few days or weeks of the onset of symptoms In acute caseous tuberculosis death often follows in a few months In chronic fibro caseous tuberculosis the disease may be completely arrested or relapse at intervals in other instances it progresses steadily in spite of all treatment to a fatal termination In fibroid tuberculosis the disease may become completely arrested or smoulder gently for many years

CLASSIFICATION —That suggested by the Joint Tuberculosis Council has been adopted by the British Ministry of Health

Patients suffering from any form of tuberculosis should be divided into *Class A*—cases in which tubercle bacilli have never been discovered in any exudate excrement discharge or tissue (T B minus) *Class B*—cases in which tubercle bacilli have been found at any time in any exudate excrement discharge or tissue (T B plus)

The extent of the pulmonary lesion is best described by radiological zones as follows The upper zone—that area above a straight line running through the lower borders of the anterior ends of the second ribs The middle zone—that area bounded by the above line and one running through the lower borders of the anterior end of the fourth ribs The lower zone—the remainder of the lung below the middle zone

Respiratory cases in both Classes A and B should be further sub divided in three groups as follows *Group 1*—Cases with slight constitutional disturbance if any

deleterious effect Involvement of the genito urinary system increases the severity of the disease especially if the kidneys or bladder are affected If the epididymis alone is involved the prognosis is not materially affected as the lesion can be dealt with surgically although the administration of a general anæsthetic may cause spread of the pulmonary disease For this reason when operations are urgently needed on these patients gas and oxygen basal anæsthetics local or spinal anæsthesia should be insisted on

The rate of sedimentation of the erythrocytes (see p 1023) has proved to be a valuable aid to prognosis A persistently rapid rate is unfavourable

Treatment —PROPHYLACTIC —The prophylaxis of tuberculosis involves a consideration of public health questions dealing with the purity of the milk supply the inspection of meat sanitation and housing the early diagnosis of tuberculosis the examination of contacts and the segregation of ' open cases Inoculation with B C G vaccine (attenuated living bovine bacilli) is being used increasingly in Great Britain for protective vaccination of children and especially of contacts It is now generally advised for Mantoux negative reactors on hospital staffs All these questions are considered in the general article on Tuberculosis Mass radiography using miniature films has been used for investigating the incidence of unsuspected tuberculosis in certain groups of the population such as factory workers and men in the forces The average findings in this series shows that in about 0 5 per cent of those examined shadows suggestive of tuberculosis are found although the incidence of active disease is considerably lower If these cases can be adequately treated it should tend to check the spread of infection

The treatment of Mantoux negative reactors working in sanatoria or hospitals has recently received attention The Joint Tuberculosis Council advises that they should be weighed and have their blood sedimentation estimated monthly and their Mantoux reaction tested at least every 3 months preferably every month When the reaction becomes positive they should be examined radiologically and clinically According to the degree of the signs and the radiological appearances they may either be allowed to work part time and rest in bed when off duty or taken off duty till it is clear that no progressive lesions are developing Those showing definite symptoms must be treated as cases of active disease

CURATIVE —This varies with the type and stage of the disease In all acute or febrile cases treatment should be commenced at home or in a nursing home or hospital where the patient can be under careful observation in bed The various forms of treatment which may be considered are—(1) sanatorium treatment (2) home or institutional treatment (3) dietetic treatment and personal hygiene (4) climatic treatment, (5) graduated rest exercise and labour (6) medicinal treatment (7) specific measures (8) operative treatment (9) symptomatic treatment

1 SANATORIUM TREATMENT —This constitutes the best mode of treatment for early and for certain types of chronic disease but is totally unsuited for acute febrile or very active cases The advantages obtained are (*a*) the patient learns the most suitable mode of life and the methods employed to check the spread of the disease (*b*) the housing is specially designed and the climatic conditions are good (*c*) the dietary is abundant and adapted to the patient s needs (*d*) there is constant skilled medical supervision and the daily routine is adapted to the actual physical condition of the patient

On arrival a newcomer is kept in bed for a few days in order that his resting temperature may be observed and the necessary examinations carried out. If there is pyrexia rest in bed must be enforced until the temperature falls to normal If the temperature rises above 99 F when the patient is up return to bed is usually necessary The routine of sanatorium treatment varies in different institutions the most important divergence being whether or not a system of graduated exercise is employed In nearly all an hour s recumbent rest is enforced before lunch and dinner

Patients with resolute and persistent personality are more likely to persevere with treatment and to recover than those of weaker moral fibre

The prognosis is greatly affected by the type of the disease Acute miliary tuberculosis used to be rapidly fatal in 100 per cent of cases, whereas with the use of streptomycin the mortality is less than 50 per cent and in acute caseous tuberculosis although the prognosis is very grave, recovery may occur In fibro caseous tuberculosis the prognosis is most uncertain and difficult to forecast Every factor must be carefully considered and the response to treatment noted The best outlook is in fibroid disease, which often undergoes complete and permanent arrest

SYMPTOMS IN THEIR RELATION TO PROGNOSIS —Persistent cough, by exhausting the patient and disturbing sleep, is often unfavourable

The amount of sputum is usually dependent upon the type of disease and upon the presence of secondary infection and may therefore be of value in prognosis.

The significance of tubercle bacilli in the sputum —The figures obtained at the Midhurst Sanatorium, over a period of 8 years in which the after-history of the patients was traced for the ensuing 6 years, show that the prognosis is best in closed' cases, but that it is nearly as good in those cases in which the tubercle bacilli disappear from the sputum during the sanatorium treatment Persistence of bacilli in the sputum is an unfavourable sign The actual number of bacilli in the sputum and the presence of beading' have no definite prognostic significance

Cases commencing with hæmoptysis progress more satisfactorily than those with other modes of onset, chiefly because they are diagnosed earlier Hæmoptysis occurring later may exert an unfavourable influence either indirectly by spreading the disease into previously healthy portions of the lungs or actually by the loss of blood

If dyspnœa is not due to attacks of bronchial spasm, it has usually an unfavourable significance

The temperature affords a clue to the type and activity of the disease, and is thus a valuable aid to prognosis Profuse and persistent night sweats or marked anorexia especially when occurring early in the disease are grave signs Tachycardia due to toxæmia, signs of cardiac failure œdema and albuminuria are of bad omen The blood pressure is thought by some to be a useful guide, systolic figures below 100 mm Hg being unfavourable, whereas a rise of pressure may be associated with amelioration of the disease In fibroid lesions the pressure may be raised throughout.

THE EXTENT OF PHYSICAL SIGNS —The activity of the disease rather than its extent is often the more important factor in determining prognosis but both factors are of importance since the outlook is always more serious if both sides are affected especially if cavitation is present The development of compensatory emphysema is of value only as an indication of fibrosis in the tuberculous portion of lung and therefore of chronicity

THE INFLUENCE OF COMPLICATIONS ON PROGNOSIS —Generally speaking, the presence of complications increases the gravity of the disease Involvement of the larynx is a serious complication especially when accompanied by dysphagia but complete recovery may take place if the pulmonary lesion is quiescent In early cases spontaneous pneumothorax occasionally acts favourably, but when it develops in association with extensive tuberculosis and especially if it progresses to pyopneumothorax it is almost invariably fatal though, if the disease is unilateral, surgical measures may prove successful

Pleural effusion often has a beneficial influence by diminishing the movements of a lung in which there is an early tuberculous focus

Secondary catarrhal affections tend to increase the cough and expectoration and may lead to further spread of the disease

Meningitis is still a very serious complication but streptomycin has made a great difference to the prognosis Tuberculous peritonitis or enteritis is a very grave complication but fistula in ano often occurs in chronic cases and exerts no marked

culous toxins and that if the exercise was carefully graduated a condition of increasing immunity through the use of autogenous tuberculin would arise However even if the theory has no certain foundation and excess effort is to be avoided, progressive occupational therapy is essential

6 MEDICINAL TREATMENT —There has been a long series of drugs used in the treatment of tuberculosis One no longer used which had a long vogue and an extensive optimistic literature was sanocrysin It took over 10 years before it fell into virtual disuse because the natural course of pulmonary tuberculosis is so uncertain that it takes a great many years and a great many cases before one can conclude any thing from studying the results of treatment

Streptomycin starts with the very great advantage that it is known to cure many cases of two diseases previously incurable miliary tuberculosis and tuberculous meningitis In pulmonary tuberculosis it is thought to be most effective where there is fresh infiltration and less so or ineffective in chronic fibrocaseous tuberculosis

Streptomycin is usually given in doses of 1 g daily It may be given continuously over a period of 2 or 3 months at a time but it is more usual to give two to four courses of injections each lasting 2 or 3 weeks with an interval of about 2 weeks between each course The object of the interval is to diminish the likelihood of toxic reaction One of these is giddiness due to labyrinthine damage Another is nerve deafness which sometimes follows the prolonged dosage given in miliary tuberculosis or tuberculous meningitis A less common toxic reaction is an urticarial or erythematous rash with or without pyrexia The effectiveness of streptomycin is limited by the tendency for drug resistance to develop The organisms rarely become resistant before a minimum period of 14 days but the number of resistant strains rapidly rises in proportion until after about 3 months it is maximal unless measures are taken to prevent it It has been found that the simultaneous administration of other drugs such as sodium aminosalicylate (P A S) or isoniazid diminishes or delays the appearance of strains resistant to streptomycin or to themselves

Streptomycin in combination with one or other of the above drugs is given generally in cases of miliary tuberculosis or tuberculous meningitis It is usually given in acute caseous pneumonia or broncho pneumonia

Physicians differ as to its use in other forms of the disease Many oppose its use in fibrocaseous disease because it is not very effective because the patient may spread streptomycin resistant disease and because if the patient subsequently requires surgery it would probably not be possible to get a maximal effect in the prevention of local spread of infection during surgical intervention On the other hand it may serve to prevent or limit the local spread of broncho pneumonia which bring the patient s life progressively to an end Some use it in tuberculous pleural effusion or in minimal tuberculous lesions in an attempt to arrest the disease in its incipient stage They discount the possibility of losing the eventual protective effect of streptomycin by the hope that they will have rendered improbable the necessity of surgical intervention Many use it in early infiltration with the same object It is rarely given in *primary* tuberculosis although it is probably wise to give it in very young children or in the so called progressive primary in which a massive primary lesion slips directly into a post primary stage with incidental danger of miliary spread It is generally used to prevent spread during resection or thoracoplasty

It appears to be effective in the treatment of tuberculous laryngitis tuberculosis of the bronchi ulcers of the tongue and possibly of the intestines

The permanent place of streptomycin in therapy will take many years to determine Sodium aminosalicylate has a bacteriostatic effect *in vitro* but is not apparently bactericidal It has been used by itself in treatment and good results have been claimed Probably its only important use is in combination with streptomycin to delay the development of resistant strains of tubercle bacilli The dosage recommended is 3 to 4 g four times a day making a total daily dosage of 14 to 18 g Large

After 3 months stay it is usually possible to decide whether the patient is responding to treatment, and if so it should if possible, be prolonged for at least another 3 months or until the sputum is free from tubercle bacilli

2 HOME AND INSTITUTIONAL TREATMENT —Treatment at home in nursing homes or in special hospitals is essential in early cases with fever and in cases in which it is necessary to establish the diagnosis Home treatment is also usually necessary on return from sanatorium or climatic treatment, if arrest is incomplete An endeavour should always be made to carry out the principles inculcated at the sanatorium and the patient should be under regular medical supervision Advanced cases are best looked after in special institutions

3 DIETETIC TREATMENT AND PERSONAL HYGIENE —It is desirable to graduate the diet in each case so that the *patient is restored to the previous maximum* weight but in order to accomplish this, the food should be slowly increased and all ideas of enforced overfeeding discountenanced A total calorie value of 3000 to 3500 is usually ample but, if the patient is performing heavy work as much as 4000 may be necessary Meat, fish, eggs and fats are usually well tolerated It is not often necessary to give large quantities of milk when the patient is on a full dietary

In all cases in which there is expectoration the patient should be clean shaven Great care must be taken in the disposal of sputum to ensure that it does not become dry and that flies do not have access to it All patients who are up should carry special sputum flasks while those who are in bed should have sputum cups suitably covered and containing disinfectant The sputum should be burnt, or, if this is impossible it should be emptied into the water closet after disinfection with carbolic acid or other simple or cheap disinfectant

Smoking is best avoided in cases of active disease or laryngeal tuberculosis and in no instance should inhaling be allowed Sun bathing and injudicious uncontrolled sun exposure are dangerous and often activate quiescent lesions Patients should be strongly warned of this danger

4 CLIMATIC TREATMENT —Climate is not now considered to be so important as it used to be Broadly speaking, bracing areas with cool dry air, porous soil and moderate height promote a feeling of well being stimulate the appetite and the mind and are more favourable than damp low lying relaxing sites Countries with a high mean temperature and high humidity are unsuitable for tuberculous patients With proper treatment patients are just as likely to recover in the sanatorium in their home area as by travelling far afield There is no special virtue in Switzerland except that the mountains are an agreeable background to prolonged bed rest and the air and atmosphere are crisper and cleaner than in this country In any case early treatment and control are best carried out in this country Patients with diminished vital capacity due to fibrosis or emphysema should not be sent to sanatoria at over 2 000 ft

5 GRADUATED REST AND EXERCISE —Rest is an essential preliminary part of the treatment of active tuberculosis Even apyrexial patients benefit from several weeks of bed rest Pyrexial cases must be kept in bed until the temperature has remained normal for several weeks It is an advantage to allow patients up for toilet purposes but acute cases with a high initial temperature may require periods of absolute rest when no movement or activity on the part of the patient is allowed Rest treatment should be controlled by careful temperature observations Rectal temperatures or 5 minute mouth readings must be used and even minor variations should be regarded as significant

The patient is allowed to get up by degrees starting with 1 hour daily increasing to 6 or 8 hours If still apyrexial the patient is allowed walking exercise of 1 or 2 miles daily The system of graduated exercise which Paterson instituted at the Frimley Sanatorium caused a revolution in sanatorium treatment in that it introduced a progressive occupational therapy into the previously otiose and sterile stagnation of sanatorium life Paterson had the theory that muscular exercise *liberated tuber-*

invariably occurs and the treatment by artificial pneumothorax cannot be repeated In some cases of bilateral disease which is active but not very extensive in either lung a cautious use of bilateral artificial pneumothorax has proved practicable and helpful but very great care is necessary in adjusting the pressures

There are certain dangers in the procedure These are now rare, and they can usually be prevented by careful attention to the technique Death has occurred from air embolism when the needle has accidentally been put into a blood vessel in the lung It is for this reason that air should never be allowed to flow unless there is a clear negative swing of the manometer showing that the needle is in the pleural cavity If the lung is adherent to the chest wall owing to pleural adhesions or if the needle is pushed in too far it may be inserted into the lung or into a pulmonary cavity the manometer will then show a swing above and below the zero line instead of entirely below it. Under these circumstances no air should be allowed to enter The needle may be inserted into a blood vessel In this case the manometer pressure will rise above zero and blood may appear in the glass section inserted in the rubber tube leading from the manometer to the needle The needle should be withdrawn immediately lest air should enter the vessel

If the pleura is found to be adherent at the site of the first puncture another attempt may be made elsewhere *e g* just below the inferior angle of the scapula This spot may be selected for the initial puncture in left sided cases where there is marked cardiac displacement In cases in which localised band or cord adhesions prevent adequate collapse it is often possible to cut them by electrocautery or dia thermy through an operating thoracoscope thus ensuring completely effective collapse. This is called internal pneumolysis Provided that the lung is sufficiently relaxed to permit closure of cavities the persistence of adhesions does not necessarily make the treatment ineffective

Over-collapse may lead to atelectasis of a lobe probably due to bronchial obstruction It is not uncommon after adhesion section Its persistence is a serious complication as it may lead to pleural effusion empyema or bronchiectasis but often the lung re-expands as the excess air is absorbed Pleural effusions sometimes occur during treatment Small amounts of fluid in the costophrenic gutter occur at some time in the majority of cases Large effusions sometimes occur requiring aspiration They do not necessarily prevent continuation of treatment but are often followed by progressive obliteration of the pleural cavity and occasionally they become purulent

Other rare complications are pressure pneumothorax following injury to the lung during induction or refill and very rarely secondary infection of the pleural cavity

(*b*) *Phrenic paralysis* —Crushing of the phrenic nerve results in a paralysis lasting from 8 to 18 months The paralysed diaphragm is elevated at rest and rises during inspiration The degree of collapse varies very much but occasionally very satisfactory lung relaxation occurs It is rarely used as the only treatment but is usually combined nowadays with pneumoperitoneum

The indications are the same as those for pneumothorax and it is used where pneumothorax has failed or is being postponed for some reason Phrenic crush should not be used if thoracoplasty is likely to be necessary as the operation cannot be performed until the diaphragm recovers its mobility Occasionally phrenic crush is followed by permanent paralysis

(*c*) *Pneumoperitoneum* —Air introduced into the peritoneal cavity raises the dia phragm and produces partial collapse of the bases of the lungs As in an artificial pneumothorax the injections of air must be repeated at intervals to compensate for absorption In order to achieve the best results, the diaphragm on the affected side should be paralysed by crushing or evulsion of the phrenic nerve In a favourable case a pneumoperitoneum will raise the diaphragm by several inches and this, together with the abolition of the diaphragmatic movement, relaxes and rests the lower part of the lung The operation is indicated in cases of cavitating tuberculous

doses have been used but they often produce gastric disturbances which may necessitate the abandonment of the treatment, and the doses given above are usually the largest that can be tolerated by the majority of patients Small initial doses and the routine administration of the drug with meals often limit the gastro-intestinal disturbances The drug may produce erythematous rashes with pyrexia in a small percentage of cases

Isoniazid (isonicotinic acid hydrazide) is also used in the treatment of pulmonary tuberculosis, the usual dose being 100 mg in the morning and 50 mg in the evening but it may be increased to a total of 200 mg per day in divided doses It is bactericidal *in vitro* and good results are obtained in treatment with this substance combined with streptomycin Resistance to isoniazid develops rapidly but appears to be delayed when it is combined with streptomycin and there seems to be some probability that it delays the development of streptomycin resistance as effectively as does sodium aminosalicylate Its status in the treatment of pulmonary tuberculosis cannot be finally estimated at the present moment

The sulphones and thiosemicarbazones are of doubtful value, and liable to produce methæmoglobinæmia and anæmia in the first instance and jaundice and possible liver damage in the second

7 COLLAPSE THERAPY—This form of treatment has the object of relaxing the affected lung and allowing it to contract towards the hilum In this way it provides rest allows cavities to collapse and therefore heal and probably prevents the spread of tuberculous disease in the collapsed lung and prevents the formation of cavities

The following methods of collapse therapy are available—artificial pneumothorax, phrenic paralysis pneumoperitoneum extra pleural pneumothorax and thoracoplasty

(*a*) *Artificial pneumothorax*—This treatment is the oldest method of collapse therapy, dating from Forlanini of Pavia in 1898 In suitable cases it is still the most effective method of collapse therapy

If old and dense pleural adhesions are present, it is impracticable If there is much emphysema or cardiac embarrassment it involves risk It is also of value in certain cases of repeated severe hæmoptysis Tuberculous laryngitis or enteritis are not contraindications providing that other conditions are suitable Sterile air is introduced into the pleural cavity and the lung allowed to collapse The method of induction of artificial pneumothorax is as follows A preliminary subcutaneous injection of gr $\frac{1}{3}$ of papaveretum (Omnopon) is given half an hour before the start. The patient lies on the sound side with the head low and supported on a pillow A second pillow is placed under the chest to expand the intercostal spaces The skin and the tissues down to the pleura are anæsthetised with 2 per cent procaine hydrochloride solution after the application of iodine The site usually chosen is in the sixth intercostal space in the mid axillary region The pneumothorax apparatus is carefully tested to make sure that it is in working order A special pneumothorax needle is attached to the machine by a rubber tube which is pinched to show that the manometer oscillations are free and the needle is then pushed through the intercostal space until the pleural cavity is reached The apparatus is then adjusted so that the intrapleural pressure can be observed No air should be introduced until the manometer shows a normal negative pressure range with inspiration, of 5 to 10 or more cm of water This is the test of entry into the pleural space and when this is established 200 to 300 c cm of sterile air may be allowed to enter the pleural cavity The final pressures are then recorded and the needle is withdrawn A refill is given next day and another after 2 more days the quantities of air introduced being determined by the final pressures which should be kept slightly negative Subsequent refills are gradually spaced out to a week, then 10 days and later to 2 3 and 4 weeks intervals The usual custom now is to maintain the collap e for 3 years or longer If the condition of the patient is satisfactory re expansion may then be permitted cautiously It should be remembe ed that after expansion pleural adhesion almost

is rarely fatal except in advanced cases but causes alarm out of proportion to the danger Reassurances and sedatives help to allay fear but sedatives should be adapted to circumstances and not overdone If the bleeding is severe and continual drip transfusion should be given

Artificial pneumothorax has been used to stop hæmorrhage when the affected side is known although it is rarely needed and indeed it is probably seldom that it could be performed It has however been successfully employed on several occasions when all other measures had failed

Congo red and other blood coagulants are of no value

Gastro-intestinal symptoms—Anorexia or dyspepsia are usually due to toxæmia and improve with rest Sometimes the milk diet increased fat cod liver oil and so forth which these patients are often given are the cause of the dyspepsia Alkalis are often helpful Patients should be advised not to swallow their sputum and told why they should not as otherwise they often ignore this advice

If diarrhœa develops a low residue diet with a high vitamin content should be given Diarrhœa usually occurs in terminal cases and tincture of opium will help to relieve it.

Insomnia is often a troublesome symptom and every endeavour should be made to obtain a good night s rest by administration of mild hypnotics and by relieving distressing cough and pain

The treatment of the complications of pulmonary tuberculosis is described under their respective headings The rehabilitation of patients discharged from sanatoria is an important subject to which considerable attention is being devoted and involves a consideration of the advisability of establishing training centres or industrial colonies for consumptives These are proving of very great value

MINIMAL TUBERCULOSIS

As a result of mass radiography the significance of minimal lesions requires especial study There are various definitions of what constitutes a minimal lesion but the exact definition is not important

These are usually small nodular discrete lesions found in the upper part of either lung usually below the first or second or third ribs there may be one or more than one they do not give rise to any physical signs and their presence can only be detected by radiological examination These are post primary lesions and are not accompanied by glandular enlargement. Under observation these shadows may rarely recede and disappear or may become denser as they are replaced by fibrous tissue or calcification They may on the other hand eventually cavitate or there may appear in the adjacent lung small areas of infiltration with progressive disease These latter changes may occur months or more often years after their first detection

Observation has now shown that at least 30 per cent develop into progressive disease and the proportion may really be higher At the present time partly owing to shortage of hospital and sanatorium accommodation in many clinics patients showing these radiological shadow are merely kept under observation without treatment only receiving treatment when progressive disease has occurred It is probable that most cases of progressive tuberculosis with sputum would at some time previous have shown these minimal lesions These lesions should always therefore be treated seriously as they present a golden opportunity for treatment at an early stage If successfully treated progressive tuberculosis might become rare and the incidence of tuberculosis diminish

It has already been stated that some of these lesions become calcified and give no further trouble but there is at the present time no method of determining which lesions will remain static and which will progress Patients showing these lesions

lesions in the lower lobe when an artificial pneumothorax has failed It is particularly successful in the treatment of cavities in the apex of the lower lobe (dorsal segment) Care is necessary in the technique to avoid the risk of air embolism This treatment is used where pneumothorax has failed or as a prelude to pneumothorax treatment when the activity of the tuberculous disease in the lung has subsided sufficiently to make pleural effusion less likely to follow artificial pneumothorax It is less effective than pneumothorax treatment but quite effective in some cases

(*d*) *Extra pleural pneumothorax* —This treatment was the logical development of pneumothorax treatment when it was impossible to collapse the lung by orthodox pneumothorax treatment on account of adhesions Collapse is obtained by separating the pleura and the underlying lung from the chest wall inside the endothoracic fascia and then by maintaining the separation by putting air in the space thus formed It fell out of use because of the frequency of secondary infection and spread of disease to the extra pleural space The development of antibiotics has led to some revival of the operation

(*e*) *Thoracoplasty* —This operation was originally used in cases where artificial pneumothorax had been attempted and failed because of adhesions or because cavities remained patent in the partially collapsed lungs It is however, often used as a primary form of collapse It is particularly used to collapse apical cavities The operation involves division of a variable number of ribs sometimes combined with apicolysis to allow the lung to collapse by mobilisation of the chest wall It is a serious operation but good results are obtained The more radical thoracoplasties are not so often done nowadays and resection is replacing many thoracoplasties

(*f*) *Resection* —All the surgical measures previously described are designed to put the diseased lung in a favourable state for natural healing to occur Resection aims at eradicating the lesion itself It is a less mutilating operation than thoracoplasty and more effective than thoracoplasty in dealing with cavities of the lower lobe It is being increasingly used to remove apical cavities tuberculomata and tuberculous bronchiectasis Only time can show whether too optimistic a view is taken of its value by some enthusiasts Its use is limited by the multiplicity of tuberculous lesions Resection may very well replace many forms of collapse therapy but its least debatable value at present is in putting a full stop to disease already arrested by other methods No form of surgical treatment is a substitute for general treatment

8 Symptomatic Treatment —When cough is ineffective it may be relieved by a sedative lozenge or linctus containing diamorphine or codeine or by the well known liquorice lozenge If there is difficulty in bringing up the sputum a simple saline mixture is of value such as sodii bicarb gr 10, sodii chlorid gr 3 sp chlorof min 10 and aq anethi dest ad fl oz 1

Night sweats —Free ventilation is the key to prevention The windows should be widely open The clothing and bedclothes should be as light as consistent with warmth Feather or rubber mattresses should be avoided In very severe cases a rush or thin cork mattress has been recommended

Fever —Rest in bed up to the extent of absolute rest is the best means of lowering the temperature

Hæmoptysis —In cases in which the sputum is only streaked no special treatment is required Moderate hæmoptysis with expectoration of 3 or 4 oz of blood requires more active measures The patient should be put to bed and as there is usually anxiety given a sedative either chloral hydrate or morphine gr ⅛ In profuse or persistent hæmoptysis the patient should be confined strictly to bed and if it is known from which side the bleeding has occurred he should be on the affected side to prevent the blood from being aspirated into the sound lung

He should have one or two pillows and should not be kept too immobile as the blood may cause collapse of one or more lobes unless it is coughed up Hæmoptysis

Symptoms—These are in general identical with those of the chronic forms of pulmonary tuberculosis such as cough, expectoration, which may be offensive, dyspnœa fever and night sweats.

Complications and Sequelæ—These are usually due to the other localisations of the organism but in addition empyema and bronchiectasis may be mentioned

Diagnosis—This can only be established by the discovery and identification of the organism in the sputum and the discharge The characteristic "sulphur grains are not invariably present and may escape notice unless looked for carefully In any obscure case of pulmonary disease in which tubercle bacilli are not found after repeated search the possibility of actinomycosis should be considered and direct films should be specially examined

Course—This is progressive and may lead to asthenia emaciation and death

Prognosis—This is serious although some cases respond well to treatment.

Treatment—(See p 196) Surgical treatment of local abscesses or of empyema may be required Penicillin is often effective in doses of 1 million units daily for several weeks Large doses of potassium iodide are traditional

PULMONARY ASPERGILLOSIS

Ætiology—Infection of the bronchi and lungs sometimes occurs by *Aspergillus fumigatus* more rarely by *A nidulans* The disease has been most frequently observed in France It occurs among pigeon breeders and hair sorters and combers The former acquire the disease from the process of artificial feeding from transferring grains in the mouth to the beak of the bird the latter from the use of rye flour in cleaning the hair Millers and farm labourers have also been the subjects of the disease

Pathology—The fungus induces nodular formations in the lung tissue somewhat resembling aggregated tubercles Bronchitis patchy lobular consolidation and fibrosis result Emphysema bronchiectasis and cavity formation may follow A secondary aspergillosis may occur in chronic cases of bronchitis or lung disease but is of little clinical importance

Symptoms—Primary aspergillosis produces symptoms similar to those of bronchitis broncho-pneumonia or pulmonary tuberculosis according to the localisation and degree of the lesions The sputum may be blood stained or definite hæmoptysis may occur There is generally wasting with irregular fever

Diagnosis—The condition has to be differentiated from pulmonary tuberculosis and from other varieties of pneumonomycosis It may be suspected when repeated examinations of purulent sputum do not show tubercle bacilli It is however a rare disease and even if the fungi are found they may be secondary invaders or contaminants

Course—Acute broncho pneumonic forms may be fatal in a few weeks or months The chronic lesions may extend to years and arrest with fibrosis is not uncommon

Treatment—This consists in avoiding further infection and giving large doses of potassium iodide Open air measures and general tonic treatment are also to be recommended All Aspergilli are completely resistant to penicillin

FARMER S LUNG (see p 1015)

OTHER MYCOTIC INFECTIONS

Fungi of the genera *Blastomyces* (*Oidium Coccidioides*) and *Sporotrichum* are well known to produce cutaneous affections simulating chronic gummatous or tuberculous lesions They may also give rise to pulmonary disease producing symptoms like those of tuberculosis

should be put to bed Five minute or rectal temperatures should be carefully charted and the sputum, if any, should be examined, if there is no sputum laryngeal swabs or gastric washings should be examined and cultivated, although at this stage tubercle bacilli are rarely found Observation of the temperature chart will often show minor yet important deviations from the normal, even in patients who have no symptoms A raised sedimentation rate should be accepted as evidence of activity, but the sedimentation rate is rarely raised and a normal sedimentation rate does not exclude a progressive lesion If all these observations are negative it may be considered safe to discharge the patient and keep him under observation A wiser course however is probably to give these cases courses of streptomycin and isoniazid Whether progressive disease can be prevented by this treatment it is not yet possible to say but certainly it does not always prevent spread of the disease Artificial pneumothorax does appear to prevent spread and cavitation and should be induced in young patients or patients who show definite evidence of activity as shown by pyrexia a positive sputum or radiological change in the lesion In the United States of America these lesions are often excised and incidentally it has been shown that they represent a localised broncho pneumonia Resection may well become the treatment of choice but the difficulty of adopting drastic measures of treatment or even of admitting the patients for observation and assessment is that the patient has no symptoms whatever The name minimal lesion is not a happy one, as it suggests an insignificant lesion but once it is generally realised that these shadows like the cloud no bigger than a man's hand may be the presages of storms to come, they will receive the serious treatment which they deserve and the whole picture of pulmonary tuberculosis may be altered in our own time

THE PULMONARY MYCOSES (PNEUMONOMYCOSES)

A number of fungi produce pulmonary lesions Considerable confusion exists in regard to their nomenclatures, and at the present time it is difficult to give accurate accounts of them The pulmonary mycoses have one feature in common in that they produce chronic pulmonary lesions practically indistinguishable clinically from those of the chronic forms of pulmonary tuberculosis

Among the varieties of mycotic infection at present separated clinically may be mentioned—Actinomycosis, Sporotrichosis (see p 196) Aspergillosis Torulosis (see p 197) North and South American Blastomycosis (see pp 198, 199), Coccidioidosis (see p 200), and Histoplasmosis (see Appendix *i*)

PULMONARY ACTINOMYCOSIS

Ætiology —The general characters of the streptothrix group of organisms are described in the section on Actinomycosis (see p 193) A large proportion of cases show the first lesions in the head and neck regions but primary pulmonary cases occur and are probably more frequent than is generally recognised

Pathology —In the primary pulmonary cases the distribution of the lesions is at first very similar to that of tuberculosis and the disease may extend in an identical manner In the forms due to spread from other organs such as the liver the base of the lung may be first involved while in cases extending down from the neck the path of the infection is apparent

Owing to the tendency of the lesions to spread by contiguity subcutaneous abscesses may form and simulate caries of the ribs Pleural adhesion is the rule but occasionally empyema results When a subcutaneous abscess ruptures or is opened the characteristic sulphur granules may be found although this is not invariable The skin around the sinuses which result is often puckered in a somewhat characteristic fashion

bronchi may complicate the course Bronchiectasis has already been mentioned and tuberculosis may occur as a complication

Diagnosis —This is often difficult and sometimes inconclusive Obscure pulmonary signs in a syphilitic subject should arouse suspicion The Wassermann reaction should be determined and other indications of syphilis looked for in all fibrosing and destructive lung conditions when no tubercle bacilli are found in the sputum These cases have never been common in modern memory and are becoming rarer Other syphilitic lesions such as aortic regurgitation are usually present. The difficulty of diagnosis is increased by the association of syphilis and tuberculosis mentioned above

Course and Prognosis —Where the lesions are localised and can be recognised early the course is favourable if anti syphilitic treatment is applied Where fibrotic changes occur leading to bronchiectasis the course is less favourable and in the destructive form it is serious An inter-current tuberculous infection increases the gravity of pulmonary syphilis

Treatment —When a diagnosis of pulmonary syphilis has been established vigorous anti syphilitic treatment should be carried out Its beneficial effect is undoubtedly promoted by open air treatment In cases where tuberculosis coexists with syphilis anti syphilitic treatment is strongly recommended especially by French physicians

NEW GROWTHS IN THE LUNGS

Both benign and malignant tumours may occur in the lungs the latter being the more common

Ætiology —Malignant tumours occur more frequently in the male sex in the ratio of 5 to 1 carcinoma is rare before the age of 40 The lung is now the commonest site of cancer in the male Some of the apparent increase is due to more accurate diagnosis but there is probably a genuine increase It has been observed that cancer of the lung is most commonly found in smokers and Doll and Hill have produced suggestive figures showing that heavy cigarette smokers have a much greater incidence than non smokers Further studies are necessary to determine the importance of cigarettes as an ætiological factor

Pathology —Benign tumours found in the lungs usually arise in the bronchial mucous glands or in the bronchi They include adenoma fibroma lipoma and chondroma (see p 972)

Malignant tumours may be primary or secondary The primary growths are carcinoma or sarcoma It is probable that all varieties of bronchial carcinoma arise in the basal cells of the bronchial mucous membrane Certain types are described the squamous celled carcinoma the adeno or columnar celled carcinoma and the oat celled tumour The squamous celled carcinomata form a clearly differentiated group in which may be included columnar celled growths with duct and acinar formation the remainder are sometimes known as undifferentiated tumours consisting of more primitive types of cells These types however may be combined so that any one particular carcinoma may vary histologically in different areas Sarcoma is extremely rare and most tumours thus described prior to 1928 were in fact anaplastic carcinomata Metastatic carcinoma may arise from primary tumours in *breast stomach intestines liver pancreas prostate or kidney* and metastatic sarcoma most often results from tumours of bone Chorion epithelioma also give rise to secondary deposits in the lungs

Primary malignant tumours are usually unilateral but secondary growths are often multiple Dissemination in the lungs may occur by spread through the bronchi or vessels and a condition of miliary carcinomatosis is at times produced The pleura is often affected by direct extension Infiltration of or pressure upon the mediastinal structures frequently occurs

Castellani has described various broncho pulmonary conditions due to species of the genus *Monilia* (*Candida*) including the "tea tasters' cough" and "tea factory cough" Another fungus *Mucor mucedo*, has been found in the sputum, and is regarded as pathogenic to man

All these moulds produce bronchitic symptoms and mild infections while more severe forms simulate pulmonary tuberculosis The diagnosis in each case depends upon the recognition of the fungus, and the treatment recommended is large doses of potassium iodide

PULMONARY HISTOPLASMOSIS

This is described in the article on Histoplasmosis (see Appendix *i*)

TOXOPLASMOSIS

This is described in the article on Toxoplasmosis (see Appendix *v*)

SYPHILIS OF THE LUNGS

Ætiology—Clinically recognisable pulmonary syphilis is a rarity, but syphilitic lesions occur in the lungs in both the congenital and acquired forms of the disease

Pathology—Even post mortem it is often difficult to establish the syphilitic nature of the pulmonary lesions found in cases of syphilis owing to the fact that they tend to the formation of scars presenting no characteristic features

Congenital syphilis—The essential changes are—(1) Round celled infiltration with eventual fibrosis, starting round the bronchi and spreading to the inter alveolar framework, (2) periarteritis of the smaller arteries and (3) desquamation and de generation of the epithelium of the alveoli and bronchi Gummata may be present, but are rare Spirochætes can be demonstrated in the lesions by Levaditi s method The microscopic appearances comprise the "white pneumonia" of Virchow and an interstitial pneumonia which is commoner although both conditions are fre quently associated White pneumonia is found in premature or still born infants and in those dying soon after birth The condition may be widespread or localised The affected areas are firm consolidated smooth and greyish white in colour There are no interstitial changes, and the consolidation is due to the filling of the alveoli with desquamated degenerating epithelial cells

In the commoner interstitial form the lung is firmer harder and darker grey in colour and the connective tissue is mainly involved To this condition the term "pancreatisation of the lung" has been applied by Rogers

Acquired syphilis—Syphilitic lesions of the bronchi have already been described in the section on diseases of the bronchi Gummata may occur in or around the intra pulmonary bronchi or in the lung tissue They may be single or multiple and vary in size from that of miliary granules to a hen s egg They are said to be more common in the deeper parts of the lung near the roots and in the lower lobe They undergo changes similar to those occurring in gummata elsewhere but tend more to fibrosis and contraction than to softening Owing to these secondary changes the following conditions may result broncho pneumonic processes widespread fibrosis and con traction with pleural adhesion bronchiectasis and occasionally excavation

Symptoms—Small gummata may be latent and give rise to no symptoms or signs When fibrosis occurs they are similar to those of pulmonary fibrosis from other causes It is generally recognised that in rare cases a destructive process occurs formerly called "syphilitic phthisis" and almost exactly similar in its clinical mani festations to those of caseous or fibro caseous tuberculosis

Complications and Sequelæ—Syphilitic lesions in the larynx trachea or

pathy there is a progressive atrophic paresis predominantly affecting the limb girdles bulbar palsy diplopia and ptosis may occur the tendon jerks are diminished or absent there are often subjective sensory manifestations such as pain cramps or paræsthesiæ but objective sensory changes are rare

Diagnosis—This is difficult in early cases and not easy in some advanced ones It not infrequently happens that metastases especially in brain or bone, afford the earliest manifestations to be recognised Difficulties may arise in connection with pulmonary tuberculosis fibrosis and gumma of lung aneurysm pericardial and pleural effusion and enlargement of the mediastinal glands due to Hodgkin s disease or tuberculosis The whole body should be searched for evidence of malignant disease elsewhere The sputum should be examined repeatedly for tubercle bacilli and for cellular elements and a radiographic examination made of the chest Localised pulmonary collapse thus demonstrated may be a very early indication By the stereoscopic method excellent evidence of pulmonary neoplasms is often obtainable Lipiodol injection and radiographic examination or tomography may demonstrate the obstruction of a bronchus by the growth which often presents a tapering or rat tail appearance Bronchoscopy is essential in the diagnosis of bronchial carcinoma Temporary artificial pneumothorax may be helpful in diagnosis particularly in differentiating simple tumours in the periphery of the lung growths in the mediastinum and in the chest wall

The Pancoast tumour may give rise to special difficulty It has to be differentiated from syringomyelia cervical rib apical pulmonary tuberculosis and secondary sarcoma

Course—This is progressive the patient gradually losing strength and dying from cachexia or some intercurrent affection

Prognosis—Apart from those cases in which early recognition may in suitable conditions render lobectomy or pneumonectomy with removal of the growth possible this is hopeless death occurring in a few weeks or being delayed for 2 or 3 years The possibility of a successful pneumonectomy is more favourable with differentiated than with undifferentiated types of growth In the latter the growth tends to be more *infiltrating* and the glands are more likely to be involved

Treatment—Benign tumours are often capable of complete removal with gratifying success

In malignant growths lobectomy or dissection pneumonectomy with complete removal of the growth is only practicable for cases recognised early in which there are no secondary deposits

Radiotherapy may be useful by diminishing local pressure and relieving symptoms but cure by this method is rare

Useless cough should be checked by sedative lozenges or a linctus Dyspnœa due to pleural effusion may be relieved by tapping with or without air replacement but the fluid often reaccumulates rapidly Pain should be relieved by analgesic drugs and in the later stages those containing opium or its alkaloids may be required

TROPICAL DISEASES OF THE LUNG

Paragonimiasis or Distomatosis—Paragonimiasis is a disease contracted in parts of Korea Japan Formosa or China by bathing in or drinking infected water or eating raw crabs or crayfish The symptoms of cough hæmoptysis and pleurisy are caused by the invasion of the lung by flukes

Pulmonary Schistosomiasis—This disease is found in North and South Africa and particularly in Egypt It also occurs in South America and the West Indies It is caused by the invasion of the lung by the ova of *S hæmatobium* or *S mansoni* The ova form tubercles and there is an obliterating endarteritis of the arterioles

Symptoms —Simple tumours except adenomata are pathological curiosities, and as a rule only produce symptoms when they cause obstruction of a bronchus or press on mediastinal structures (see pp 972 1094)

The early symptoms of malignant growths are slight, and consist of malaise with, perhaps, cough and expectoration Later when the growth becomes more extensive and exerts pressure on or involves the larger bronchi, mediastinum or pleura, they are more noticeable Pain, dyspnœa and loss of weight with cachexia usually develop and the cough and expectoration are more marked The latter is often of the typical " currant jelly " or " prune juice appearance due to altered blood Microscopically groups of large fatty cells, or irregular epithelial cells may be seen Malignant cells may be found in 60 per cent of cases by Dudgeon s wet method There are usually no definite physical signs until the tumour causes pressure upon the bronchi, medi astinum or deep thoracic veins or nerves The chest wall may bulge locally, owing to the presence of a growth near the surface or it may be retracted if a main bronchus is obstructed An actual subcutaneous swelling caused by the tumour eroding through the chest wall may be visible Enlarged veins often run across the chest, and one *or other arm may be swollen or œdematous if there is mediastinal obstruction* Vocal fremitus is often unaffected but is increased when the growth is near the surface, and diminished if pleural effusion has occurred The percussion note over a moderate-sized tumour is impaired and may be extremely dull, more often the dullness is due to collapse of the lung The breath sounds vary with the size and position of the growth and with the displacement or pressure effects produced They may be weak, or loud and stridorous The stridor is usually unilateral Adventitious sounds depend upon the presence of complications such as bronchitis Some degree of fever often occurs The supra clavicular and axillary glands are not infrequently enlarged and evidence of malignant disease may be present in other parts of the body such as the abdomen

One special variety of apical carcinoma is the superior pulmonary sulcus or Pan coast tumour, which gives rise to a somewhat characteristic or suggestive clinical picture The chief symptoms are pain in the shoulder inner side of the arm and fore arm together with weakness and wasting of the small muscles of the hand Paralysis of the cervical sympathetic on the same side develops There is usually localised dullness at the extreme apex Radiological investigation reveals a sharply defined apical shadow with destruction of the posterior part of the first three ribs and some times localised vertebral erosion Pancoast suggested that these tumours may arise from remnants of the fifth branchial cleft

Complications and Sequelæ —*Bronchitis is nearly* always present in some degree Pulmonary collapse fibrosis bronchiectasis emphysema, gangrene hæmop tysis pleural effusion abscess and empyema are sometimes observed The effusion is frequently bloodstained In cases of primary malignant disease of the lungs *secondary deposits may occur in other parts of the body such as glands* brain supra renals, heart and bones Cardiac arrhythmia such as auricular fibrillation may result from direct invasion of the pericardium or myocardium

Carcinoma of the lung may be accompanied by neurological syndromes which are not due to secondary deposits and which may cause symptoms before the car cinoma Four types of neuropathy are recognised subacute cerebellar degeneration sensory neuropathy polyneuritis and motor neuropathy The clinical manifestations are not always clear cut and there may be evidence of multiple lesions in the nervous system The characteristic picture of subacute cerebellar degeneration is of a rapidly progressive ataxia and dysarthria diplopia euphoria and dementia are common and there may be *pyramidal and sensory changes In sensory neuropathy* the pre senting symptoms are pain and paræsthesiæ in the limbs and ataxia there is peri *pheral sensory impairment and ataxia*, absent tendon reflexes and only slight muscular weakness In polyneuritis there are motor and sensory changes In motor neuro

pathy there is a progressive atrophic paresis predominantly affecting the limb girdles, bulbar palsy diplopia and ptosis may occur, the tendon jerks are diminished or absent there are often subjective sensory manifestations such as pain cramps or paræsthesiæ but objective sensory changes are rare

Diagnosis —This is difficult in early cases and not easy in some advanced ones It not infrequently happens that metastases especially in brain or bone afford the earliest manifestations to be recognised Difficulties may arise in connection with pulmonary tuberculosis fibrosis and gumma of lung aneurysm pericardial and pleural effusion and enlargement of the mediastinal glands due to Hodgkin s disease or tuberculosis The whole body should be searched for evidence of malignant disease elsewhere The sputum should be examined repeatedly for tubercle bacilli and for cellular elements and a radiographic examination made of the chest. Local ised pulmonary collapse thus demonstrated may be a very early indication By the stereoscopic method excellent evidence of pulmonary neoplasms is often obtainable Lipiodol injection and radiographic examination or tomography may demonstrate the obstruction of a bronchus by the growth which often presents a tapering or 'rat tail' appearance Bronchoscopy is essential in the diagnosis of bronchial carcinoma Temporary artificial pneumothorax may be helpful in diagnosis particularly in differentiating simple tumours in the periphery of the lung growths in the medias tinum and in the chest wall

The Pancoast tumour may give rise to special difficulty It has to be differ entiated from syringomyelia cervical rib apical pulmonary tuberculosis and secondary sarcoma

Course —This is progressive the patient gradually losing strength and dying from cachexia or some intercurrent affection

Prognosis —Apart from those cases in which early recognition may in suitable conditions render lobectomy or pneumonectomy with removal of the growth possible this is hopeless death occurring in a few weeks or being delayed for 2 or 3 years The possibility of a successful pneumonectomy is more favourable with differentiated than with undifferentiated types of growth In the latter the growth tends to be more infiltrating and the glands are more likely to be involved

Treatment —Benign tumours are often capable of complete removal with gratify ing success

In malignant growths lobectomy or dissection pneumonectomy with complete removal of the growth is only practicable for cases recognised early in which there are no secondary deposits

Radiotherapy may be useful by diminishing local pressure and relieving symptoms but cure by this method is rare

Useless cough should be checked by sedative lozenges or a linctus Dyspnœa due to pleural effusion may be relieved by tapping with or without air replacement but the fluid often reaccumulates rapidly Pain should be relieved by analgesic drugs, and in the later stages those containing opium or its alkaloids may be required

TROPICAL DISEASES OF THE LUNG

Paragonimiasis or Distomatosis —Paragonimiasis is a disease contracted in parts of Korea Japan Formosa or China by bathing in or drinking infected water or eating raw crabs or crayfish The symptoms of cough hæmoptysis and pleurisy are caused by the invasion of the lung by flukes

Pulmonary Schistosomiasis —This disease is found in North and South Africa and particularly in Egypt It also occurs in South America and the West Indies It is caused by the invasion of the lung by the ova of *S hæmatobium* or *S mansoni* The ova form tubercles and there is an obliterating endarteritis of the arterioles

Symptoms —Simple tumours except adenomata are pathological curiosities, and as a rule only produce symptoms when they cause obstruction of a bronchus or press on mediastinal structures (see pp 972 1094)

The early symptoms of malignant growths are slight, and consist of malaise with, perhaps, cough and expectoration Later when the growth becomes more extensive and exerts pressure on, or involves the larger bronchi, mediastinum or pleura, they are more noticeable Pain dyspnœa and loss of weight with cachexia usually develop and the cough and expectoration are more marked The latter is often of the typical "currant jelly" or "prune juice" appearance due to altered blood Microscopically groups of large fatty cells or irregular epithelial cells may be seen Malignant cells may be found in 60 per cent of cases by Dudgeon s wet method There are usually no definite physical signs until the tumour causes pressure upon the bronchi medi astinum or deep thoracic veins or nerves The chest-wall may bulge locally owing to the presence of a growth near the surface or it may be retracted if a main bronchus is obstructed An actual subcutaneous swelling caused by the tumour eroding through the chest wall may be visible Enlarged veins often run across the chest, and one or other arm may be swollen or œdematous if there is mediastinal obstruction Vocal fremitus is often unaffected, but is increased when the growth is near the surface, and diminished if pleural effusion has occurred The percussion note over a moderate sized tumour is impaired and may be extremely dull, more often the dullness is due to collapse of the lung The breath sounds vary with the size and position of the growth and with the displacement or pressure effects produced They may be weak or loud and stridorous The stridor is usually unilateral Adventitious sounds depend upon the presence of complications such as bronchitis Some degree of fever often occurs The supra clavicular and axillary glands are not infrequently enlarged and evidence of malignant disease may be present in other parts of the body such as the abdomen

One special variety of apical carcinoma is the superior pulmonary sulcus or Pan coast tumour which gives rise to a somewhat characteristic or suggestive clinical picture The chief symptoms are pain in the shoulder, inner side of the arm and fore-arm together with weakness and wasting of the small muscles of the hand Paralysis of the cervical sympathetic on the same side develops There is usually localised dullness at the extreme apex Radiological investigation reveals a harply defined apical shadow with destruction of the posterior part of the first three ribs and some times localised vertebral erosion Pancoast suggested that these tumours may arise from remnants of the fifth branchial cleft

Complications and Sequelæ —Bronchitis is nearly always present in some degree Pulmonary collapse fibrosis bronchiectasis emphysema gangrene hæmoptysis pleural effusion abscess and empyema are sometimes observed The effusion is frequently bloodstained In cases of primary malignant disease of the lungs secondary deposits may occur in other parts of the body such as glands brain supra renals heart and bones Cardiac arrhythmia such as auricular fibrillation, may result from direct invasion of the pericardium or myocardium

Carcinoma of the lung may be accompanied by neurological syndromes which are not due to secondary deposits and which may cause symptoms before the car cinoma Four types of neuropathy are recognised subacute cerebellar degeneration sensory neuropathy, polyneuritis and motor neuropathy The clinical manifestations are not always clear cut and there may be evidence of multiple lesions in the nervous system The characteristic picture of subacute cerebellar degeneration is of a rapidly progressive ataxia and dysarthria diplopia, euphoria and dementia are common and there may be pyramidal and sensory changes In sensory neuropathy the pre senting symptoms are pain and paræsthesiæ in the limbs and ataxia there is peri pheral sensory impairment and ataxia, absent tendon reflexes and only slight muscular weakness In polyneuritis there are motor and sensory changes In motor neuro-

pathy there is a progressive atrophic paresis predominantly affecting the limb girdles, bulbar palsy diplopia and ptosis may occur the tendon jerks are diminished or absent there are often subjective sensory manifestations such as pain cramps or paræsthesiæ but objective sensory changes are rare

Diagnosis—This is difficult in early cases and not easy in some advanced ones It not infrequently happens that metastases especially in brain or bone afford the earliest manifestations to be recognised Difficulties may arise in connection with pulmonary tuberculosis fibrosis and gumma of lung aneurysm pericardial and pleural effusion and enlargement of the mediastinal glands due to Hodgkin s disease or tuberculosis The whole body should be searched for evidence of malignant disease elsewhere The sputum should be examined repeatedly for tubercle bacilli and for cellular elements and a radiographic examination made of the chest Localised pulmonary collapse thus demonstrated may be a very early indication By the stereoscopic method excellent evidence of pulmonary neoplasms is often obtainable Lipiodol injection and radiographic examination or tomography may demonstrate the obstruction of a bronchus by the growth which often presents a tapering or rat tail appearance Bronchoscopy is essential in the diagnosis of bronchial carcinoma Temporary artificial pneumothorax may be helpful in diagnosis particularly in differentiating simple tumours in the periphery of the lung growths in the mediastinum and in the chest wall

The Pancoast tumour may give rise to special difficulty It has to be differentiated from syringomyelia cervical rib apical pulmonary tuberculosis and secondary sarcoma

Course—This is progressive the patient gradually losing strength and dying from cachexia or some intercurrent affection

Prognosis—Apart from those cases in which early recognition may in suitable conditions render lobectomy or pneumonectomy with removal of the growth possible this is hopeless death occurring in a few weeks or being delayed for 2 or 3 years The possibility of a successful pneumonectomy is more favourable with differentiated than with undifferentiated types of growth In the latter the growth tends to be more infiltrating and the glands are more likely to be involved

Treatment—Benign tumours are often capable of complete removal with gratifying success

In malignant growths lobectomy or dissection pneumonectomy with complete removal of the growth is only practicable for cases recognised early in which there are no secondary deposits

Radiotherapy may be useful by diminishing local pressure and relieving symptoms but cure by this method is rare

Useless cough should be checked by sedative lozenges or a linctus Dyspnœa due to pleural effusion may be relieved by tapping with or without air replacement but the fluid often reaccumulates rapidly Pain should be relieved by analgesic drugs and in the later stages those containing opium or its alkaloids may be required

TROPICAL DISEASES OF THE LUNG

Paragonimiasis or Distomatosis—Paragonimiasis is a disease contracted in parts of Korea Japan Formosa or China by bathing in or drinking infected water or eating raw crabs or crayfish The symptoms of cough hæmoptysis and pleurisy are caused by the invasion of the lung by flukes

Pulmonary Schistosomiasis—This disease is found in North and South Africa and particularly in Egypt It also occurs in South America and the West Indies It is caused by the invasion of the lung by the ova of *S hæmatobium* or *S mansoni* The ova form tubercles and there is an obliterating endarteritis of the arteriol s

These eventually cause pulmonary hypertension, angiomata and pulmonary artery dilatation

Pulmonary Amœbiasis —Invasion of the lung by *Entamœba histolytica* is usually by direct spread from a hepatic abscess although primary amœbic abscesses presumably embolic, have been described Invasion is usually accompanied by effusion or empyema The sputum coughed up from the abscess is described as being like anchovy paste and this is an apt description although similar sputum sometimes occurs in pulmonary abscess not of amœbic origin

Amœbiasis is a disease of world wide distribution It is not strictly a tropical disease but it only assumes serious proportions where sanitation is defective or human excrement is used in agriculture

Emetine is usually effective in this condition combined with penicillin or other antibiotics

CYSTIC DISEASE OF THE LUNG

Ætiology —Cysts may be congenital or acquired

(i) *Congenital cysts* are lined with respiratory epithelium and have a wall in which elements of the bronchial wall are present They do not always possess any obvious connection with a patent bronchus and are often associated with congenital abnormalities of the heart or skeleton or with cystic disease in other organs The following varieties are described (*a*) The solitary cyst This may occasionally be inflated to balloon like size and be mistaken for a pneumothorax (*b*) Multiple cysts giving rise to either a soap bubble or honeycomb appearance of a lobe or lobes The cysts usually contain air but may contain clear mucinous fluid or they may become full of pus if they are secondarily infected

(ii) *Acquired Cystic Disease* —Some doubt has been expressed as to whether cystic bronchiectasis is an acquired condition or represents infection of a congenital cystic condition of the lung It is however probable that cystic bronchiectasis is the result of bronchiectasis acquired in early life Cystic bronchiectasis has a characteristic multilocular radiological appearance usually in a lower lobe Operative removal is advisable to prevent complications although this type of bronchiectasis often has a relatively benign course In staphylococcal pneumonia thin walled abscesses or cysts often appear and usually disappear by reabsorption Occasionally the cysts remain and may give rise to no symptoms although they are sometimes associated with bronchiectasis They are probably caused by local alveolar distension due to the check valve action of a partly occluded bronchus The 'ring shadows of tuberculosis are of a similar nature and cysts and cavities similar in character occasionally occur in asthmatics

Symptoms —These vary with the variety of cyst present The large balloon cyst met with in infants or young children may result in severe respiratory and cardiac distress In such cases there is cyanosis dyspnœa and displacement of the trachea mediastinum and heart to the opposite side of the chest The percussion note over the cyst is hyper resonant and the breath sounds are absent Solitary cysts often give rise to no symptoms and are only discovered on routine radiographic examination When infected the clinical features may resemble those of lung abscess or bronchiectasis With multiple medium sized or small cysts no symptoms usually appear until infection occurs though hæmoptysis may occur early When infected toxæmic symptoms develop such as loss of weight irregular fever cough and expectoration which is sometimes offensive Clubbing of the fingers may then soon be noted On examination scattered areas of slight dullness and weak air entry with a few persistent râles may be detected

Course, Complications and Sequelæ —The onset of complications usually

leads to the development of symptoms which call for investigation Thus spon taneous pneumothorax may result from rupture of a cyst In other cases suppuration occurs in the cyst with the formation of lung abscess bronchiectasis or empyema Cerebral abscess may be a late sequel

Diagnosis —This is suggested by radiography and by lipiodol examinations and possibly tomography If the space in the cyst is free from fluid the radiographic appearances must be differentiated from those of pneumothorax an emphysematous bulla a thin walled tuberculous cavity or in some cases a diaphragmatic hernia If the cyst contains fluid further investigations are required to exclude the presence of such conditions as lung abscess encysted pleural effusion or empyema hydatid cyst dermoid cyst or a blood cyst A definite diagnosis can sometimes only be made after operation by microscopical examination of a portion of the cyst

Prognosis.—This varies with the type of cyst present the development of com plications and the treatment adopted In many cases the prognosis is good apart from rupture or infection In the large balloon cyst there is risk of sudden death during an attack of distension

Treatment —The large balloon cysts which are causing respiratory and cardiac embarrassment call for immediate treatment by the insertion of a needle Subse quently the only hope of recovery lies in pneumonectomy

When the cysts are infected, treatment by postural drainage should first be adopted Failure usually follows attempts at surgical drainage or collapse opera tions If the cysts are unilateral and infected the only hope of cure lies in radical removal of the portion of lung involved either by segmental resection lobectomy or pneumonectomy and so in bilateral cases it necessarily follows that no radical cure is possible

SARCOIDOSIS OF THE LUNG

Sarcoidosis is really a generalised disease but it occurs often enough in the lungs to merit a separate description

There are two main pulmonary forms One in which the glands are predominantly involved and one in which there is generalised pulmonary infiltration There is however no hard and fast division between the two conditions The enlarged hilar glands are the commonest form and have been found to be common as a result of mass radiography They usually cause no symptoms at all but they may be associated with other lesions in the bones the eyes or the skin Sometimes the discovery is made as the result of a chest radiograph suggested by the appearance of erythema nodosum The differential diagnosis is from the adenitis of primary tuberculosis lymphosarcoma and Hodgkin s disease and other conditions causing mediastinal glandular enlargement

The glands of sarcoidosis are usually discrete from each other well demarcated and bilateral They may persist for months but their disappearance can often be measured in weeks The Mantoux test is usually negative The generalised pul- monary form sometimes follows the glandular form but if it always does the glandular enlargement stage is often missed The infiltration has the radiological appearance of miliary tuberculosis pneumoconiosis or carcinomatosis The nodules may be as small as the nodules of miliary tuberculosis but are sometimes larger and coarser The hilar glands are often enlarged but not necessarily so The commonest physical signs are similar to those of miliary tuberculosis namely generalised crepitations or fine râles

Symptoms —There are often no symptoms at all in either form and the absence of symptom is often strikingly at variance with the extensive radiological findings Shortness of breath and slight cough are sometimes complained of

Course—The enlarged hilar glands often disappear in a few weeks or months Sometimes the glands remain visibly enlarged after the main enlargement has dis appeared *The miliary type of lesion* may disappear completely with the passage of months but more frequently some striated opacity suggestive of fibrosis remains in some areas Occasionally diffuse generalised fibrosis leading to cor pulmonale is described as a late result of miliary sarcoidosis While cases of diffuse pulmonary fibrosis have been described as cases of sarcoidosis there is often no pathological evidence at post mortem of any sarcoid changes

Cavitation has occasionally been observed in cases diagnosed as sarcoidosis Naturally such an event suggests a diagnosis of tuberculosis but cavitation probably occurs occasionally without tuberculous involvement Some cases of sarcoidosis eventually develop pulmonary tuberculosis but this is not evidence that sarcoidosis is a form of tuberculosis any more than is, for example pneumoconiosis which is often complicated by tuberculosis *The course of sarcoidosis is usually benign*

Diagnosis—This is almost entirely radiological and therefore open to errors of interpretation Occasionally the presence of enlarged groups of glands or the co-existence of other sarcoid lesion confirms the prescriptive diagnosis In the majority of cases the Mantoux test is negative

Treatment—Most cases recover during or in spite of treatment Streptomycin may be worth trying Calciferol in large doses is sometimes given and cases have recovered during either of these treatments Corticotrophin and cortisone are reported to produce symptomatic relief with or without streptomycin but are not usually necessary

HYDATID DISEASE OF THE LUNG

Hydatid cysts may develop in the lung in patients infected by the ova of the *Tænia echinococcus*

Ætiology—Man is the intermediate host of this parasite, and becomes infected directly or indirectly from the dog The modes of infection and the life history of the parasite are elsewhere considered (p 324) Males are more often affected and the condition is commoner amongst agricultural labourers especially amongst shepherds and dog handlers *In Great Britain it is occasionally found in Wales* It is common in the more primitive rural districts of the continent and especially in Argentina Australia New Zealand and the Middle East

Pathology—Hydatid cysts have been described in the lungs in from 5 6 to 16 8 per cent *of cases of hydatid disease in different parts of the world* The right lung is more often the site of the disease than the left, and the cyst is usually basic though it may occur in the upper parts of the lung It is generally supposed that infection of the lung is usually secondary to the liver the ova reaching the lung through the diaphragm but the occurrence of primary lung hydatid suggests the possibility of the embryo gaining access to the general blood stream and thus reaching the lung by the pulmonary artery There is as a rule, a single cyst in the lung but multiple or multilocular cysts are occasionally observed The cyst may become as large as a cricket ball but usually ruptures before it reaches this size *It has the same structure* as hydatid cysts of other organs with ectocyst and endocyst It may develop brood capsules and daughter cysts but is often sterile in this situation

The reactive changes in the lungs are at first irritative and congestive but eventu ally some fibroid changes occur producing a more or less *definite fibroid* capsule around the ectocyst The overlying pleura may become inflamed thickened and adherent when the cyst grows near the surface Rupture may occur into a bronchus into the pleura pericardium or peritoneum or occasionally into the aorta or pul monary vein Rarely the contents of a small cyst may *become inspissated* thus producing spontaneous cure

Symptoms—Until the cyst becomes large enough to cause irritation there may be no symptoms but sooner or later cough and expectoration develop The latter is generally mucoid and frequently bloodstained Dyspnœa becomes apparent and pain results if the pleura is involved The signs may be diminished vocal fremitus localised dullness and weak or absent breath sounds and voice sounds over a limited area generally in the lower lobe A few râles may be audible round the dull area Occasionally with a large cyst there may be some bulging on the affected side, and hydatid fremitus has been described The heart may be displaced in rare cases Radiographic examination generally shows a suggestive rounded shadow with very little change in the surrounding lung except in chronic cases where some fibrosis may be observed

Some degree of eosinophilia is common but not invariable. When rupture into a bronchus occurs there is usually sudden copious expectoration of watery fluid containing hooklets Daughter cysts and parts of the ectocyst may be coughed up and lead to dyspnœa and even suffocation from laryngeal obstruction

After rupture spontaneous cure may result if the ectocyst is expectorated More commonly the cavity becomes infected and the symptoms and signs become those of chronic abscess (see pp 324 1002) Rupture into the pleural cavity produces great pain dyspnœa cyanosis and shock similar to the condition induced by pneumothorax Rupture into the pericardium or into a vein is usually quickly fatal When rupture occurs into a serous cavity urticaria and severe toxic symptoms sometimes develop

Diagnosis—The clinical features of pulmonary hydatid may be suggestive of pulmonary tuberculosis pleural effusion or new growth Diagnosis may be difficult before rupture occurs after this the discovery of hydatid hooklets or pieces of cyst wall may establish the diagnosis In suspicious cases the radiographic findings may be of great assistance and confirmatory evidence may be obtained from cytological and serological examination The former frequently shows eosinophilia and the latter gives complement deviation when a suitable antigen such as extract of hydatid cyst wall is used A precipitin reaction may also be obtained with the fluid from another cyst The Casoni intradermal test with the appropriate antigen has established itself as having special diagnostic value

Course—This is generally progressive though occasionally spontaneous cure occurs either before or after rupture More commonly the cyst causes increasing pressure or irritative symptoms and eventually rupture or suppuration produces acute manifestations

Prognosis—The prognosis is serious owing to the risks of rupture and suppuration Spontaneous cure is rare but can occur After rupture into a bronchus recovery may ensue but more commonly abscess formation results Rupture into a serous cavity is frequently fatal Early surgical treatment either before or after rupture improves the outlook

Treatment—Aspiration of the cyst, either exploratory or therapeutic is to be avoided If the cyst can be diagnosed or localised before rupture the lung should be exposed by thoracotomy the pleura stitched together and the cyst incised the endocyst removed and the cavity drained Suppuration of a pulmonary hydatid must be treated as a pulmonary abscess Removal of a lobe containing a single cyst may be the operation of choice

THE PNEUMONIAS

The ideal classification of the pneumonias would be an ætiological one and the old morbid anatomical distinction between lobar pneumonia on the one hand and lobular or broncho pneumonia, on the other would be even less important than it

has already been made by modern therapy Scadding has devised a classification which ignores rigid morbid anatomical divisions and divides pneumonias into two main groups

(1) The acute specific pneumonias whose ætiology is more or less known, and
(2) The aspiration pneumonias which include most of what used to be called broncho pneumonias

By using the term aspiration pneumonia' he wished to indicate that the inflammatory changes were due to the aspiration of infected secretion, where there has been a breakdown in normal defensive mechanisms Most of the broncho pneumonias follow atelectasis produced by aspiration and the term aspiration therefore, has ætiological significance It is unlikely, however, to replace the well established term broncho pneumonia which suggests very well pneumonia following bronchial infection No exact classification can be made without certainty about ætiology and the distinction between various anatomical types is often impossible and unnecessary as they merge into each other In the descriptions which follow, no hard and fast classification has been attempted but the anatomical division into lobar pneumonias and broncho pneumonias will be referred to since it has sometimes diagnostic significance

LOBAR PNEUMONIA

This term has become almost synonymous with pneumococcal pneumonia and this condition will be described first although as will appear, other pneumonias assume approximately lobar form

PNEUMOCOCCAL PNEUMONIA

Ætiology —*Predisposing causes* —Pneumonia may occur at any age It is common in children up to the sixth year the incidence being about equal in the two sexes It is commonest between the ages of 15 and 40 when there is a preponderance in the male sex of 2 or 3 to 1 It is also a frequent terminal malady in the aged of both sexes It may be doubted whether race has much influence although in America and in the Rand mines and throughout Africa the incidence and mortality among the black races are both high Pneumonia is met with all over the world In this country its seasonal incidence is well marked it is uncommon in the summer and autumn and is most prevalent from November to March Although pneumonia is as a rule endemic and sporadic in its incidence it is generally admitted that localised epidemics occur Urban conditions defective sanitation overcrowding and insufficient ventilation all conduce to the incidence of pneumonia It is not uncommon to obtain a history of several previous attacks Although the disease often attacks those in normal robust health there can be no doubt that debilitating conditions and diseases predispose to it among them being chronic nephritis, diabetes over fatigue exposure and alcoholic excess

Exciting causes —The exciting cause in most cases is the presence of the pneumococcus (*Str pneumoniæ*) It may be the only pathogenic organism found in the lung lesions and in the sputum but not infrequently others such as streptococci, staphylococci or *H influenzæ* are also present

The pneumococcus —The pathogenicity of the pneumococcus has been the subject of an interesting study by Cole Dochez Avery and Gillespie and more recently by Georgina Cooper and her co workers Originally three types were described Types I II III which together account for more than 50 per cent of all cases The remainder were included in a group referred to as Group IV This has now been separated into 29 other types making 32 in all by means of serological reactions

The American observers have shown that 40 per cent of contacts with cases of pneumonia due to types I and II may harbour the corresponding organism for an average of 23 days and that they may develop pneumonia from it They have further demonstrated that a convalescent patient may carry pathogenic pneumococci in his mouth for as long as 90 days from the onset of the disease They have also found pathogenic pneumococci in the dust of rooms in which patients suffering from pneumonia have been nursed The significance of this work is obvious It confirms the view that pneumonia is an infectious disease capable of being spread by carriers by the convalescent patient and by the dust of rooms

Although the pneumococcus is the specific exciting cause its activities are often determined by some other factor such as chill exposure over exertion or injury The presumption is that these conditions lower the general resistance of the individual and thus impair the defensive mechanisms Post operative pneumonia may be a further instance of this but doubtless some supposed cases are in reality due to lobar collapse

Pathology—The pneumococcus is found in the pulmonary lesions and elsewhere when complications occur In some patients it is found in the blood These are referred to as bacteriæmic cases and are usually more severe and often associated with complications Experimental investigations on animals indicate that the avenue of infection to the lungs is by way of the trachea and bronchi the blood infection being secondary to the pulmonary lesion Four stages are commonly described in the process by which the lung becomes consolidated and returns to normal namely engorgement red hepatisation grey hepatisation and resolution

In the stage of engorgement the affected part of the lung is slightly enlarged deep red in colour and heavier than normal although it still crepitates and floats in water The pleura over it may be injected and lustreless and may even show early fibrinous exudate On section the hyperæmia is obvious and there may be some œdema On squeezing frothy bloodstained fluid exudes Microscopically the engorgement of the capillaries and the swelling and partial desquamation of the alveolar epithelium are the chief changes to be noted In the stage of red hepatisation the affected area becomes completely consolidated the general aspect on section being remotely similar to liver hence the name hepatisation The pleura is now notably inflamed and may be obscured by yellow fibrinous exudate The hepatised area of lung is larger and much heavier than normal and bears the impress of the ribs upon it On section it is seen to be red in colour solid and completely airless It does not crepitate and it sinks in water The lung tissue is found to be more friable than normal On scraping the cut surface which has a granular appearance a reddish fluid is collected containing small fibrinous plugs which are practically alveolar casts Microscopically the alveoli are occupied by a coagulated exudate rich in fibrin and red blood corpuscles with scanty leucocytes and a few larger cells derived from the alveolar epithelium In the stage of grey hepatisation the lung tissue although still solid airless and non crepitant is greyish in colour softer in consistence and still more friable The surface of the section is less granular and on scraping a pale yellowish almost purulent fluid is obtained Microscopically the blood vessels are found to be relatively empty the alveoli are now incompletely filled the fibrin and red corpuscles have largely disappeared and the alveoli are occupied by leucocytes and desquamated alveolar cells In the stage of resolution the exudate becomes more liquid and its cellular constituents undergo fatty degeneration The liquefied exudate is largely absorbed although expectoration may possibly assist in its removal The lung returns to its normal spongy state and the alveolar epithelium is replaced Some pleural thickening or adhesion may however result In very severe and fatal cases the stage of resolution may be replaced by one of purulent infiltration in which the lung becomes paler softer and in places almost diffluent The scrapings are practically purulent

Although these four stages are described it should be remembered that they are

not sharply defined from one another and that they only represent special appear ances in a continuous process Consequently, although the major part of the affected area of lung may be characteristic of any one of them all four stages may be recognis able especially in cases of a spreading type The base is more often affected than other parts, and the right side more than the left, in the ratio of 3 to 2 The unaffected parts of the lung may show some catarrhal bronchitis or some degree of collateral hyperæmia or œdema Pleurisy is an integral part of the affection, but it may proceed to serous or purulent effusion Pericarditis and less frequently acute endocarditis may be found in fatal cases Pneumococcal meningitis, arthritis and otitis are very occasionally observed The liver and kidneys may show cloudy swelling and the spleen is often slightly enlarged and soft Jaundice may be observed especially in right sided cases The right side of the heart may be engorged and dilated

Symptoms —The following description is based on the symptomatology and progress of a patient untreated with antibiotic therapy There was great variation in both even before antibiotic therapy, but this has very much curtailed and altered the course of the disease The exact incubation period is not yet established, but it is short being probably from 1 or 2 days up to a week The onset is sudden and acute, with chill shivering or rigor in the majority of cases In children convulsions take the place of rigors Vomiting at the onset is not infrequent occurring in about one third of the cases Less commonly the onset is insidious, or is preceded by malaise and catarrhal symptoms The temperature rises with the rigor and, as a rule, a short dry irritating cough develops quickly, accompanied by a severe cutting pain on the affected side The pain often becomes intense, and coughing may cause the patient great distress The cough is frequently restrained as much as possible and the breathing is rapid and shallow By the second or third day the pain becomes less and the cough easier and more effective Sputum, which at first is scanty, extremely viscid tenacious and difficult to expectorate, now becomes more abundant, although remaining viscid In typical cases it is characteristically rusty at this stage containing mucus altered red blood corpuscles alveolar epithelium and large numbers of pneumo cocci In a few instances a small but definite hæmoptysis occurs Occasionally the sputum is thinner and of ' prune juice type

Sleeplessness is often a distressing symptom especially in the early and late stages In some cases there are marked cerebral symptoms Headache at the onset is common Delirium is frequent particularly in the asthenic type in apical cases and in alcoholics In the latter it may be violent and is often like delirium tremens The temperature is usually of high continuous type throughout, reaching 103 , 104° and even 105° F or more on occasions Defervescence is by crisis in about 60 per cent of the cases The most common day for the crisis is the seventh It is rare before the third or after the ninth day At the crisis the temperature falls to normal or subnormal in about 12 hours The patient often sleeps soundly at this time and may sweat profusely respiration is slower and easier and the pulse rate falls On waking a dramatic change in the condition is usually noticeable Pain and distress are ameliorated cough is loose and easy and the patient feels better, although weak Looseness of the bowels and free diuresis are not infrequent constituting the critical evacuations ' The crisis is sometimes preceded by a pseudo crisis in which a considerable fall of temperature occurs with little or no improvement in the general condition A slight post critical rise of temperature of 1 or 2° F is sometimes seen but as a rule the temperature remains subnormal for a few days and slowly returns to normal The pulse rate may be slow for a time Convalescence is generally rapid although in cases which have had marked delirium some mental confusion may be present for a day or two Defervescence by lysis is more common in asthenic patients The temperature remits and may take from 2 to 4 days to reach normal or subnormal levels

The physical signs vary with the stage of the disease At first there is some

restlessness but soon the patient assumes a dorsal decubitus or lies more on the affected side The cheeks are flushed often markedly so on the side of the lesion The eyes are bright but the expression is one of pain or anxiety A crop of herpes *on the lips is very common* The *tongue is thickly coated and white, becoming dry* and cracked in bad cases at a later stage The skin feels dry and pungently hot The alæ nasi are in action and in children a puff or grunt accompanies each expiration while the pause follows inspiration, instead of expiration The respiration and pulse rate are increased the former disproportionately so that the pulse respiration ratio becomes 3 or even 2 to 1, instead of the normal 4 or 5 to 1

In the early stage the pulmonary signs are slight At the most there is lessened movement and diminished vocal fremitus over the affected area with dubious impairment of note, weak air entry and possibly a few crepitations (indux) or pleural friction sounds vocal resonance being unaltered Of these lessened air entry is probably the most common Slight hyper resonance of the opposite lung with harsh breathing may lead to error in diagnosis as to the side affected

The signs of consolidation (hepatisation) are generally apparent on the second or third day except in cases where the disease starts deeply (central pneumonia) There is definite limitation of movement on the affected side which is however slightly increased in size as can be demonstrated by mensuration Vocal fremitus is markedly accentuated over the affected area except in massive pneumonia and friction fremitus may be palpable The note on percussion is dull, but has not the resistant stony character of that over an effusion The note above or below the consolidated area is sometimes skodaic The breath sounds are tubular, and a few crepitations may be heard but frequently adventitious sounds are absent In some cases a friction rub is audible Bronchophony and pectoriloquy are usually very marked over the consolidated area Whispering pectoriloquy usually corresponds exactly to *the area of bronchial breathing and often draws attention to it* The breath sounds in other parts may be vesicular or harsh and a few rhonchi may be present The heart is usually in its normal situation but is sometimes slightly displaced away from the affected side In later stages the signs of dilatation of the right heart may become apparent

During resolution which begins after the crisis or during lysis the tubular character of the breath sounds disappears Coarse moist sounds known as redux crepitations are heard both with inspiration and with expiration The dullness gradually diminishes and the voice sounds return to normal

In basal cases in which the diaphragmatic pleura is involved early there may be pain tenderness and abdominal rigidity simulating peritonitis perforation or appendicitis It is rare for the spleen to be sufficiently enlarged to be palpable The blood shows a leucocytosis up to 20 000 occasionally up to 50 000 in young patients A low white count in a very ill patient is an ominous sign Blood culture may yield pneumococci although this was successful in only 30 per cent of cases at the Rockefeller Institute The urine is diminished in quantity and there is a great reduction in the sodium chloride excretion until the crisis Albumin and albumose are frequently found in small quantities in the urine during the febrile stage and a few granular casts may be present The uric acid excretion is increased to two or three times the normal commencing the day before the crisis and generally falling to normal during the ensuing week This is probably due to disintegration of the exudate in the alveoli and so forms a measure of resolution although some authorities maintain that it runs parallel with leucocytosis and not with cell destruction Pneumococci can sometimes be obtained from the urine at the height of the disease

The stages of the disease are very considerably modified by the early administration of penicillin and to a less extent by the use of sulphonamides Thus if the penicillin injections are begun on the first day of the disease, when the physical signs are slight the temperature will often fall to normal within 24 to 48 hours, with a

corresponding reduction in the pulse and respiration rates The general condition of the patient also rapidly improves pain disappears and toxic symptoms are abolished On the second or third day however the physical signs of consolidation may be well marked, despite the absence of all signs of toxicity

The disease does not always follow the typical clinical course and certain varieties are described

Apical pneumonia —The consolidation may be limited to the apex or upper lobe of one lung This is more common in children, the aged and alcoholics and is often associated with marked cerebral symptoms

Creeping pneumonia (Migratory or wandering pneumonia) —The consolidation spreads irregularly in one or both lungs Partial resolution occurs but there is no true crisis, and as successive portions of the lungs become involved the temperature exacerbates, eventually falling by lysis in cases that recover

Central pneumonia —The symptoms and appearance of the patient may suggest lobar pneumonia, and yet no abnormal signs can be detected in the lungs In some of these cases there may be a deep seated consolidation which can usually be revealed by radiography A typical crisis may occur

Massive pneumonia —The bronchi as well as the alveoli may be filled with a fibrinous exudate It is a rare condition and leads to difficulty in diagnosis as the physical signs resemble those of pleurisy with effusion vocal fremitus being diminished and breath sounds weak or absent The heart however, is not displaced or only slightly so

Post operative pneumonia —It is probable that some cases that were formerly described as post operative pneumonia were in reality instances of massive lobar collapse (see p 992) At times a pneumococcal pneumonia follows the administration of a general anæsthetic but it does not present any peculiar features

Traumatic pneumonia —The fact that an injury to the chest may be followed after a short interval by a pneumonic process in the lungs has long been recognised The condition was called contusional pneumonia by Litten in 1881 Kulbs showed later that the changes in the lungs in dogs following local trauma were mainly hæmorrhagic and that the lung opposite to the side injured may be affected by contre coup In the recorded cases of traumatic pneumonia two types can be differentiated —(1) those with hæmorrhagic lesions only and (2) those showing hæmorrhagic foci with a superimposed bacterial infection The former recover rapidly the latter often lead to a fatal issue Both these types are found in blast injury to the lung produced by close proximity to explosions in air or in water

Pneumonia in children —This often presents certain characteristic features There is rarely any sputum, the expectoration being swallowed Convulsions at the onset are common The lesion is often at the apex of the lung Cerebral symptoms are frequent and empyema or otitis media often occurs as a complication

Pneumonia in the aged —This occurs frequently as a terminal infection often leading to a rapid and comparatively painless death The onset may be insidious and the physical signs slight

In *pneumonia in the insane* lobar consolidation is often observed without marked constitutional disturbance other than fever

Secondary pneumonia —Lobar pneumonia may develop during the course of certain acute specific fevers notably enteric typhus and plague It is doubtful whether a true lobar pneumonia occurs in influenza the condition to which the name influenzal pneumonia is applied being due to coalescing lobar pneumonia with hæmorrhagic extravasations

Complications —Delayed resolution not infrequently occurs the signs of consolidation persisting for weeks instead of days Frequent careful examinations should be made and possible errors in diagnosis considered such as the presence of tuberculosis or empyema Gangrene and abscess are rare but recognised complications

Dry pleurisy is an invariable accompaniment when the consolidation reaches the surface and in a considerable proportion of cases slight serous effusion occurs This occasionally becomes frankly purulent and an empyema results Bronchitis is common and may be due to a complicating secondary infection Cardiac failure is a grave occurrence and can be recognised by increasing cyanosis lividity and dyspnœa with signs of enlargement of the right heart and with enfeeblement of the heart sounds Pericarditis is not very uncommon and is a serious complication It may be dry or proceed to serous or purulent effusion Acute endocarditis sometimes of infective type occurs Abdominal complications are comparatively rare They include pneumococcal peritonitis colitis and nephritis Acute dilatation of the stomach occurs in rare cases and is usually rapidly fatal Meteorism is more common and although serious is more amenable to treatment Jaundice due to hepatitis or to hæmolysis is sometimes present

Pneumococcal meningitis supervenes in rare cases and was invariably fatal before the use of sulphonamides and penicillin Delirium has already been referred to and is especially serious when occurring in alcoholics Peripheral neuritis has been described but is very uncommon Otitis media and arthritis proceeding sometimes to suppuration occur as complications both being commoner in children A parotitis sometimes going on to suppuration is an occasional and serious complication especially in old people During convalescence thrombosis of the veins of the legs may occur in rare instances

Sequelæ of lobar pneumonia are uncommon Perhaps the most remarkable is the liability to subsequent attacks although a history of repeated attacks of pneumonia often suggests a diagnosis of bronchiectasis with recurrent pneumonitis Some permanent pleural thickening or adhesion may occur and after an empyema the usual sequelæ may result Pulmonary fibrosis (chronic interstitial pneumonia) is rare especially in comparison with its frequency after broncho pneumonia this may lead to bronchiectasis

Diagnosis —When the disease is well established and the history is available diagnosis is as a rule easy To prove the pneumococcal origin sputum examination lung puncture or blood culture is necessary

At the onset especially before the signs of consolidation develop difficulties in diagnosis often occur The initial rigor or convulsion with vomiting may suggest scarlet fever In children especially those with early apical pneumonia headache vomiting convulsions head retraction squint and even slight Kernig s sign may lead to an erroneous diagnosis of meningitis Pain in the side and cough the altered pulse respiration ratio and the presence even of slight abnormal physical signs in the chest usually suffice in both instances to suggest the correct explanation

Occasionally the onset of pneumonia may simulate an acute abdominal condition such as appendicitis or perforation of a gastric ulcer owing to referred abdominal pain sometimes with rigidity The diagnosis may be very difficult and laparotomy has not infrequently been carried out in error The history the pulse respiration ratio the absence of tenderness on rectal examination and the presence of pulmonary signs usually enable a correct decision to be made

Influenza may start acutely and simulate pneumonia but the distribution of the signs and the examination of the sputum generally serve to distinguish between them Typhoid fever less often gives rise to difficulty but some cases of pneumonia pass quickly into a typhoid state while some cases of typhoid fever develop consolidation in the first week

When consolidation is well established the chief conditions to be differentiated are—(1) Broncho pneumonia The slower onset the more prolonged course the bilateral patchy physical signs and the marked predominance of the bronchitic manifestations usually suffice to differentiate this group of conditions (2) Secondary pneumonias such as those in plague typhoid fever and influenza can be diagnosed

only from the history the associated symptoms and signs, and from the bacteriological examinations (3) Friedlander's pneumonia is rare Its course is short, its prognosis grave and it can only be recognised by bacteriological investigation (4) Massive collapse The diagnosis of this condition and its differentiation from pneumonia are discussed on p 993 (5) Acute pneumonic tuberculosis The onset and early signs may be identical with those of pneumonia The persistence of the fever its tendency to become remittent or intermittent and the occurrence of night sweats should suggest looking for tubercle bacilli in the sputum (6) Pleural effusion and empyema Differentiation is generally easy, except in cases of massive pneumonia Investigation of the position of the cardiac impulse and of vocal fremitus and resonance, affords the most valuable aid Grocco's triangle may also assist. In some cases the diagnosis can only be established by the exploring needle (7) Infarction of the lung in cardiac disease causing pain cough bloodstained expectoration and dyspnœa may simulate pneumonia The absence of fever the presence of the cardiac condition and the localised physical signs are generally characteristic (8) Acute œdema of the lung especially in mitral stenosis may suggest pneumonia Fever is generally absent the sputum is typical and the primary cause may be apparent. An attack of paroxysmal tachycardia may give rise to difficulty when it leads to dullness and crepitations at the bases but careful examination should establish the very rapid action of the heart and the evidence of venous engorgement in other parts

Course —The course depends on the type and virulence of the infection on the resistance of the patient and the method of treatment employed Since the use of sulphonamides and penicillin in treatment the course is much more favourable and the temperature usually falls to normal or subnormal in 2 or 3 days In fatal cases death commonly occurs between the fourth and tenth days although severe cases may prove fatal as early as the first or second day After the tenth day a fatal result is generally due to complications

Prognosis —Lobar pneumonia is a serious disease The prognosis is profoundly influenced by age and by recent methods of treatment It is infrequently fatal in childhood except in the first years of life After the age of 60 the mortality until the new chemo therapeutic measures were employed was from 60 to 80 per cent The New York investigations at the Rockefeller Institute demonstrated the importance of the type of pneumococcus in prognosis , thus it was found that the mortality of cases with types I and II was about 25 to 30 per cent of those with type III 50 per cent and of other types collectively only 12 per cent The mortality in Great Britain before the use of sulphapyridine about the year 1938 was never as high as in the U S A , being at the outside about 16 to 20 per cent in groups of all ages With the sulphonamides and penicillin the average mortality of all types has been reduced to about 8 per cent

The previous habits and history of the patient influence prognosis considerably chronic alcoholism doubles the risk of a fatal issue and the outlook is grave in patients who are the subjects of diabetes chronic cardio vascular disease nephritis marked debility or obesity Unfavourable indications during the course of the disease are profound toxæmia a pulse rate persistently 130 or more a blood pressure in milli metres of mercury lower than the pulse rate and a temperature remaining at 105 F or over for several days Absence of the usual leucocytosis is generally of sinister import Dilatation of the right heart with cyanosis progressing to lividity is most grave

Of complications meningitis is serious unless it responds to treatment by sul phonamides or penicillin while septic endocarditis is extremely grave Cases with abscess or gangrene although serious sometimes recover especially if operative treat ment is practicable The prognosis of those with pericarditis is serious but not uniformly unfavourable Cases with bilateral empyemata show a high mortality Late delirium is a very serious indication

Treatment —The patient should lie in a narrow bed away from a wall to facilitate

nursing The room should be well ventilated and the temperature maintained at 60° to 65 F Treatment in the open air is not advisable except in very mild weather Two important factors are rest and sleep The patient should therefore be disturbed as little as possible by the examination of the physician and by the attentions of the nurse His position in bed should be dictated by his own preference but most patients prefer to be propped up on two pillows In severe cases where the patient tends to be immobile on his back he must be turned to either side to prevent postural collapse The patient usually has no appetite during the acute stage He should however be encouraged to drink 3 or 4 pints daily of sweetened fluid flavoured with fruit juice Sweetened milk suitably flavoured should be given if liked but too much milk is not well tolerated Soups with a little extra salt help to prevent salt depletion As the temperature falls and appetite returns a digestible but high calorie diet should be encouraged

The irritating cough which is so painful at the outset should be checked by a sedative linctus but it may be necessary to inject gr $\frac{1}{12}$ diamorphine hydrochloride or gr $\frac{1}{6}$ morphine to reduce the pain and induce sleep in the early stage The application of a kaolin poultice or Antiphlogistine is traditional and may afford some relief Severe pain can be controlled by properly applied strapping This has the theoretical disadvantage of diminishing movement and thus encouraging collapse but nothing is more likely to prevent coughing up of sputum from the affected lung than severe pain If strapping is applied it should be removed as soon as possible

The sulphonamide group of drugs is very effective Sulphadimidine is probably the best for an adult and the treatment should be started with an initial dose of 3 g followed by 1 g 4-hourly until the temperature has been normal for 36 hours and then progressively diminished until the treatment stops about 5 days after the fall of the temperature The sputum should be taken for cultivation before treatment starts so that if there is no response to treatment the results of sensitivity will be available to guide any change in therapy

The dosage in children depends on the body weight, but as a rough guide an initial dose of 0 5 g should be given to a child from 0 to 1 year with a maintenance dose of 1 0 to 1 5 g in the 24 hours and from age 1 to 3 1 0 and 2 0 g to 3 0 g as maintenance and so up in proportion

If there is any doubt about the response or the patient is sensitive to sulphonamides or is very ill it is wise to give penicillin instead of or as well as the sulphonamides Particular care must be taken to see that these dehydrated patients have an adequate fluid intake and output during sulphonamide therapy

If there is any cyanosis the patient should be given oxygen preferably in an oxygen tent *The B L B mask unless carefully supervised is often ineffective and in any* case the cough and sputum complicate the use of a mask If a tent is not available the nasal catheter in the naso pharynx is better than the mask in most cases

Digitalis is often given in small doses but is probably of no value Injections of nikethamide (Coramine) are not of proved value but they are sometimes comforting to the patient and the doctor Sleeplessness is a frequent and distressing symptom In the early stages gr 10 of Dover's powder or an injection of gr $\frac{1}{6}$ or $\frac{1}{4}$ morphine are usually effective It is best to avoid morphine if the patient is cyanosed Chloral hydrate gr 20 and potassium bromide gr 20 can be tried or amylobarbitone (Sodium Amytal) gr 3 to 6 Paraldehyde min 120 with syrup of orange in 2 oz of water is safe or it can be given rectally in doses of 4 to 6 drams in 6 oz of water

If there is any tendency to delirium the patient should have tepid sponging and be given any of the sedatives mentioned previously They should not be left unattended as they are liable to get out of bed and fall down stairs or out of windows Tympanites when present is distressing and exhausting and should be treated by the passing of a rectal tube or by giving an enema Pituitary extract (0 5 ml.) or *neostigmine (1 mg) may be tried*

Streptococcal pneumonia—This is often lobular but may be confluent so as to appear lobar It usually follows streptococcal infection in other parts of the body especially the throat or the skin It is sometimes found as a secondary invader in nasal infections of the respiratory tract such as influenza or measles but it occurs as a primary infection of the lung The symptoms are often severe and the patient may appear more ill than in pneumococcal pneumonia Thin purulent effusions (sometimes bilateral) occur at an early stage and require aspiration

General treatment is as for pneumococcal pneumonias Most streptococci respond readily to sulphonamide drugs or penicillin

Staphylococcal pneumonia—Staphylococci are found as secondary invaders in viral pneumonias but they also cause a particular type of pneumonia The infection is usually blood borne but may be bronchogenic It may occur as a complication of a septicæmia or a pyæmia arising from a carbuncle perinephric abscess mastoiditis or some other focal lesion, but sometimes the source is not obvious There is con solidation of varying degree not often conforming to any exact lobar pattern, with a tendency to necrose and form thin walled distension cavities Several areas of the lungs may be successively involved Spontaneous pneumothorax may occur through rupture of the thin walled cavities but it is not always followed by empyema as might be expected and the cavities often disappear spontaneously After recovery the cavities sometimes remain as thin walled cysts Bronchiectasis may be a complication

General treatment is the same as described above but large doses of penicillin and sulphonamides should be given Many cases are resistant to penicillin but respond to the tetracyclines or erythromycin

Friedlander bacillus pneumonia—This organism causes pneumonia with a high mortality, especially in older patients Prostration and cyanosis are often striking and the most seriously ill patients have little pyrexia and often a leucopenia Death often occurs within 48 hours of onset The organisms are not sensitive to penicillin or the sulphonamides but may be to streptomycin chloramphenicol or chlortetracycline

There is a chronic form of lung infection due to this organism which sometimes follows the acute infection but may also occur insidiously The cases are often mis taken for fibrocaseous tuberculosis which they resemble

P pestis pneumonia This infection sometimes assumes a pneumonic form which is particularly lethal and infectious It has been described in epidemics in Manchuria and West Africa

Myco tuberculosis—Pneumonia due to this organism is described elsewhere but although it is now rare in Great Britain it is occasionally mistaken at the outset for pneumococcal pneumonia and it must be remembered as a possibility when a lobar pneumonia does not quickly yield to treatment

PNEUMONIAS OF VIRAL ORIGIN

Influenzal pneumonia—In 1933 Smith Andrews and Laidlaw showed that in fluenza was due to a filtrable virus of which two main strains labelled A and B respec tively have been isolated Influenza a highly contagious disease usually presents with fever marked prostration general aches and inflammatory changes in the respiratory tract Although it is often followed by marked depression it is rarely fatal in otherwise healthy adults but occasionally pandemics occur in which pneu monia occurs and the disease is rapidly and frequently fatal The pneumonia in these cases has been ascribed to secondary invaders amongst them *Hæmophilus influenzæ* streptococci staphylococci etc

Primary atypical pneumonia—Synonym, Virus Pneumonia — This diagnosis prob ably includes a varied group of diseases It was recognised before the war of 1914–1918 but came into prominence during the recent war as a result of the large epidemics which occurred amongst soldiers especially in the Mediterranean theatre

Pathology—Little is known of the post mortem findings as the mortality rate is low about 0 2 per cent Observations which have been made indicate that there is an interstitial broncho pneumonia with associated bronchitis and areas of collapse and emphysema The associated bronchi are filled with muco pus The inter-alveolar septa are infiltrated with monocytes

Symptoms—The incubation period varies from 2 to 21 days or longer The onset is often insidious with cough malaise and muscular pains Coryza may be marked at the onset or there may be pain in the chest with dyspnœa Some cases have been detected by routine radiographic examination of the lungs Generally the temperature rises to 100° to 103° F for about a week but some cases are apyrexial Cough may be very distressing occurring in paroxysms and with severe headache There is usually some mucoid sputum at times blood streaked but never rusty The sputum contains no predominating organisms but mononuclear cells are often present The physical signs in the lungs are rather indefinite One or more areas of slight dullness may be detected frequently at the bases with weak air entry and showers of medium râles heard after cough at the end of inspiration The pulse rate is often lower than would be expected from the pyrexia The white cell count is usually normal or there may be slight leucopenia and the sedimentation rate of the red cells is increased and may remain raised for some weeks or months The Wassermann reaction may be positive for a short time Cold agglutinins (auto hæmoagglutinins) have been found in the blood from the second to the fourth weeks of the illness Severe cases are also described with high irregular fever prostration a racking cough cyanosis and dyspnœa The temperature may remain raised for 2 to 3 weeks There are no typical radiological findings Woolly areas of consolida tion of varying size may be seen often at the bases resembling those seen in chronic disseminated or local pneumonia The hilar shadows are usually enlarged more so than they are in early tuberculous lesions and this may be of diagnostic importance

Complications and Sequelæ—The majority of cases are uncomplicated but a pleural effusion may be expected in about 9 per cent of cases and this may be purulent Rarely there are symptoms of encephalitis or meningism venous throm *bosis in the legs* and polyarthritis

Diagnosis—Some cases have been diagnosed as tuberculosis especially when the soft shadows are seen in the upper lobe The prolonged febrile type with relative low pulse rate and absence of leucocytosis may suggest typhoid fever The presence of eosinophils in the sputum or the blood will help to differentiate Loeffler s syndrome which sometimes resembles atypical pneumonia

Course—Febrile recurrences are not uncommon if the patient is allowed up too soon Usually the patient is able to leave hospital in about a month from the onset In some cases the radiographic shadows take 2 months or longer before they disappear

Prognosis—This is usually very good although recovery may occasionally be slow

Treatment—The patient should be kept in bed for a few days after the tempera ture has returned to normal He should not resume work until the sedimentation rate is normal and the radiographic findings are clear Penicillin and the sulphona mides are useless and the sulphonamides may be harmful Some cases respond well to chlortetracycline or chloramphenicol Steam inhalations usually relieve the cough Severe cyanosis or dyspnœa may be treated by oxygen inhalations

Psittacosis—This disease is transmitted by birds of the parrot family as its name implies but it may be transmitted by other birds such as pigeons or canaries The disease is similar to atypical pneumonia but is more severe and carries a mortality of up to 40 per cent The diagnosis should be remembered where pneumonic symp toms are found in someone who is in close contact with birds kept as pets or pro fessionally

Chloramphenicol and chlortetracycline are often effective

Q fever—This is a rickettsial disease which resembles primary atypical pneumonia from which it can only be distinguished by agglutination reactions Some of the epidemics of atypical pneumonia described in the Mediterranean theatre were of this character

PNEUMOCOCCAL LOBULAR PNEUMONIA

Synonym—Primary Broncho pneumonia

Ætiology—Pneumococcal infection in infants usually has a lobular form instead of a lobar one as in older children or adults Lobular pneumonia is really a more correct name than broncho pneumonia in this case since there is no antecedent bronchial inflammation before the lobular pneumonia It occurs equally in the two sexes and is commoner in the winter and the spring Rickets, malnutrition and debility are predisposing conditions

Pathology—Widely scattered patches of consolidation are found in one or both lungs These may be small and separated by areas of collapse or emphysema Occasionally they are almost confluent and at first sight appear like lobar pneumonia, constituting the pseudo lobar form, but careful observation shows that the distribution is lobular and that zones of incomplete consolidation or of normal lung tissue separate the solid areas If the process reaches the surface some degree of pleurisy is present although this is less than in lobar pneumonia

Microscopically the appearances approximate to those of the lobar form, the alveoli are found to be filled with exudate, in which leucocytes and desquamated epithelial cells are present, together with some fibrin and red blood corpuscles Catarrhal changes are also present in the bronchi

Symptoms—The onset is acute with vomiting and chill or convulsion as in lobar pneumonia but may be more gradual Cough cyanosis and dyspnœa develop rapidly There is no expectoration since infants and young children swallow the sputum Cerebral symptoms simulating meningitis are common The temperature rises quickly to 103 104° F or higher and the range is of the same character as in lobar pneumonia Defervescence by lysis is the rule

The physical signs are variable In cases with widespread consolidation they are very similar to those of lobar pneumonia, with dullness tubular breathing increased voice sounds and crepitations In other cases although the aspect of the infant appears characteristic of pneumonia with rapid breathing cyanosis reversed rhythm of inspiration and expiration sucking in of the lower ribs and dilation of the alæ nasi the signs are more scattered Tubular breathing and increased voice sounds may only be heard in localised patches especially in the lower lobes Crepitations are commonly present and rhonchi may be audible over both lungs

Complications and Sequelæ—These are similar to those of lobar pneumonia

Diagnosis—Pneumococcal lobular pneumonia has to be distinguished from the lobar form to which ætiologically and pathologically it is so closely related The acute onset without previous respiratory symptoms will suggest its primary character while the patchy distribution of the signs generally suffices to establish its lobular distribution The cerebral symptoms at the onset and the early absence of pulmonary signs may give rise to difficulty, as in the first stage of lobar pneumonia

Course—This is usually short the temperature falling in from 3 to 7 days but it may be more prolonged and be suggestive of tuberculosis or some other form of secondary bronchitis

Prognosis—The prognosis is generally unfavourable especially in very young or debilitated infants but has been improved by the use of sulphonamides or penicillin

Treatment.—This is practically identical with that of broncho pneumonia in children

BRONCHO PNEUMONIA

Synonyms —Lobular Pneumonia Aspiration Pneumonia Secondary Broncho pneumonia

In this condition there is inflammation of the bronchi spreading down to and involving the alveoli It is generally a catarrhal process but may go on to septic or suppurative manifestations

Ætiology —A secondary broncho pneumonia may occur at any age but is much more common in early and advanced life It is equal in its incidence in the two sexes It frequently occurs as a complication of measles whooping cough and influenza less commonly in cases of diphtheria scarlet fever and the enteric group A bronchitis starting in the larger tubes may spread downwards to the alveoli Broncho pneumonia may develop during the course of acute gastro enteritis A secondary broncho pneumonia occurs as a terminal infection in many old and debilitated persons and in those with chronic wasting or cachectic diseases and also in chronic cardio vascular conditions chronic renal disease and in many progressive nerve degenerations

Bacteriology —This is as might be expected very varied Streptococci are frequently present especially the hæmolytic variety generally associated with other organisms such as the pneumococcus *H influenzæ* staphylococci and those found in catarrhal conditions of the upper air passages *H pertussis* may be found in cases associated with whooping cough and occasionally *C diphtheriæ* in diphtheritic broncho pneumonia The importance of Friedländer's bacillus was formerly overestimated in this connection

Pathology —When from any of the above mentioned causes an inflammatory process reaches the finer bronchi the alveoli become affected in three different ways Owing to the blocking of the bronchi by secretion or exudate, small areas of collapse of lobular distribution are produced The inflammatory process extends into some or all of these and areas of lobular consolidation result Not infrequently the adjacent groups of alveoli become distended and are thus in a condition of acute emphysema The lungs are normal in size or slightly enlarged The surface presents a somewhat uneven mottled appearance There are small projecting patches of firmer consistence and reddish grey colour due to the consolidated lobules Adjacent areas may be depressed and slaty blue from lobular collapse while the intervening lung tissue is normal or pinkish and emphysematous There may be dimness or slight roughening of the pleura where the consolidated areas reach the surface but serous or purulent effusion is uncommon On section the lung is found to be congested and sometimes œdematous especially at the bases while the bronchi exude pus or muco pus from their cut ends The reddish-grey areas of consolidation are found to vary in size from a pin s head to a hazelnut They are generally more abundant in the lower lobes especially posteriorly The consolidated and collapsed areas both sink in water and do not crepitate There is often some peri bronchitis and the bronchial glands are usually enlarged Microscopically the finer bronchi and the consolidated alveoli are found to be filled with an exudate containing large numbers of leucocytes and desquamated proliferating epithelial cells but in which few red blood corpuscles and little or no fibrin are found

In the very acute condition to which the name capillary bronchitis was formerly applied consolidation may not be apparent but microscopical examination invariably demonstrates the involvement of the alveoli In influenzal broncho pneumonia the pathological changes probably commence as an exudative bronchiolitis associated with capillary hæmorrhages Secondary infections are probably responsible for the consecutive broncho pneumonic process which results in flooding of the alveoli with an exudate containing red cells but little or no fibrin

Symptoms —In the cases ensuing on bronchitis in infants or old people (formerly

called capillary bronchitis) initial symptoms may be slight and simply those of ordinary bronchitis namely *malaise slight fever and cough, with or without expectoration* The implication of the finer tubes and alveoli is usually marked by a rapid rise of temperature, great prostration, quick breathing and an irritating, persistent and often ineffective cough In children, the alæ nasi work, the lower ribs are sucked in and the pneumonic type of breathing develops The patient becomes cyanosed the pulse is rapid, 120 or more, and the respirations 50 or 60 per minute In old people, cyanosis, restlessness and delirium may occur and later the cough becomes less frequent, the patient being drowsy and tending to sink down in the bed whereas previously there was orthopnœa These symptoms are ominous and indicate failure of the respiratory centre

The physical signs are often those of bronchitis harsh or weak inspiration and prolonged expiration, sibilant and sonorous rhonchi and crepitations or crepitant râles, especially at the bases Patches of tubular breathing with increased voice sounds may develop, but are not always present

In other forms of secondary broncho pneumonia similar symptoms and signs develop more insidiously in the course of the primary disease Broncho pneumonia should be suspected when cough expectoration and dyspnœa, together with a remittent type of temperature, develop in the course of an acute specific fever or other severe illness In all forms, anorexia is common, the mouth and tongue become dry, and thirst is complained of The urine presents the usual high coloured concentrated character of febrile conditions It is often diminished in quantity, may contain a small quantity of albumin and not infrequently deposits urates

Complications and Sequelæ—These are relatively infrequent Pleurisy may proceed to effusion, and when this occurs it is often purulent Abscess and gangrene are rare but develop rather more frequently than after lobar pneumonia Other complications such as pericarditis endocarditis, meningitis and nephritis are probably due to blood borne metastasis

The most important sequel is bronchiectasis which sometimes follows this condition although it may not give symptoms for a long time afterwards Pulmonary tuberculosis is frequently described as a sequel especially after measles and may be due to inflammatory changes in the bronchial glands activating a quiescent tuberculous deposit there In many cases of tuberculosis described as following on broncho pneumonia it is more probable that the original lung affection was tuberculous

Diagnosis—The development of pulmonary symptoms and of more or less characteristic physical signs in the course of measles whooping cough or one of the other diseases mentioned above usually renders the diagnosis easy Difficulty may arise in regard to tuberculosis which in one form produces lobular pneumonic lesions with symptoms and signs indistinguishable from other varieties of secondary broncho pneumonia In any case where the fever lasts more than 3 weeks or where the signs show no tendency to resolve or are chiefly apical tuberculosis should be suspected Unfortunately in children sputum is rarely available An attempt is sometimes made to obtain it on gauze held in forceps after exciting cough by touching the fauces The mucus in the fauces may also be examined for tubercle bacilli The diagnosis may however remain doubtful until signs of softening become established

Bronchitis rarely gives rise to difficulty The fever is usually less high and of shorter duration while the physical signs are different, signs of consolidation being entirely absent Hypostatic pneumonia may have to be considered There is usually some obvious cause for this such as cardiac disease and failure or prolonged confinement to bed The temperature is generally lower and the distribution is lobar

Pleural effusion and empyema can generally be differentiated by the alteration of vocal fremitus and the displacement of the cardiac impulse In case of difficulty the exploring syringe enables a distinction to be made

Course—Secondary broncho pneumonia generally has a longer course than either

the primary form or the lobar variety of pneumonia The fever often persists in remittent type for 2 or 3 weeks and sometimes even for 2 or 3 months although in this case tuberculosis should be suspected The decline is almost always by lysis Convalescence is often slow the patient being left thin weak anæmic and debilitated

Prognosis—The prognosis in secondary pneumonia is serious Many deaths occur from this complication in the acute specific fevers particularly with measles and influenza Even the form following on severe bronchitis is frequently fatal especially in old people and in wrongly fed or debilitated infants The development of delirium of a pulse rate over 150 of marked cyanosis and dyspnœa is unfavourable In old people drowsiness sinking down in the bed and cessation of cough are very grave indications

Treatment.—The treatment is very similar to that of lobar pneumonia except that stimulant and expectorant drugs may be necessary from the first In cases due to pneumococcal infection sulphadiazine or one of the other sulphonamides should be employed (see p 22) If streptococci are established as the infecting agent one of the sulphonamide preparations should be given at once Penicillin may be given alone or with the sulphonamide preparation but antibiotic preparations are much less effective than in pneumococcal pneumonias The sputum should be tested as soon as possible in order to determine the sensitivity of the predominant organisms

The patient must be in bed and the position should often be changed so as to prevent hypostatic congestion The room should be well ventilated but without draughts and the temperature kept at 65 F both night and day Oxygen should be given if there is any cyanosis however slight The most effective method of giving it is by oxygen tent. The next most effective is by post nasal catheter The B L B mask is rarely used effectively The diet should be restricted to fluids and semi solids as in pneumonia The dry distressing cough at the onset may be loosened by giving a simple alkaline febrifuge mixture such as liq ammon acetat min 120 pot citrat. gr 10 sod bicarb gr 10 with flavouring agents such as syrup of tolu and chloroform water Later ammon carb and tinct ipecac. may be given, but large doses of expectorants are to be avoided because of their irritant effect on the stomach Opiates should not be administered except as tinct opii camphorata or possibly Dover s powder in the early stages In infants they should not be given at all

When in infants or children the bronchi are becoming blocked by the secretion within them as evidenced by increasing dyspnœa an emetic should be given For this purpose tinct ipecac or ammon carb in emetic doses is the most effective In old people ammon carb may be given in milk in doses of gr 10 two or three times a day Deep breathing at regular intervals should be encouraged

Nikethamide (Coramine) or camphor injections and cardiac tonics are of limited value but sometimes give comfort

INHALATION AND DEGLUTITION BRONCHO PNEUMONIA

Acute broncho pneumonic processes may be caused by the inhalation or aspiration of fluid or solid particles derived from the upper air passages or from other parts of the lung To this form the name of aspiration or inhalation pneumonia is applied When from any cause food particles are drawn into the bronchi and broncho pneumonia results the condition is referred to as deglutition pneumonia The resultant processes are similar and are in effect analogous to those caused by other septic or infected foreign bodies inhaled into the bronchi

Ætiology—These conditions may occur at any age but are more common in adult life They result from septic processes in the mouth naso pharynx larynx or

trachea, and from any morbid state leading to anæsthesia of the pharynx or to difficulty in deglutition They occur in association with ulcerating growths of the mouth, tongue, tonsil, pharynx or larynx and after operations for these conditions or upon the nose and throat, including tracheotomy They occur as a complication of achalasia or œsophageal pouches Aspiration broncho pneumonia may also result from vomiting during or after the administration of an anæsthetic Carcinoma of the œsophagus eroding the trachea may be a cause Diphtheritic or other forms of paralysis coma from any cause, especially cerebral vascular lesions and uræmia may lead to the passage of food particles into the air passages Recent work with opaque substances has shown that aspiration of foreign particles occurs more frequently after dental extractions and other surgical operations than is usually realised Other cerebral lesions such as abscess or tumour and bulbar paralysis can also produce the same condition Infected material may be aspirated from diseased to healthy parts of the lung, as in hæmoptysis, abscess, gangrene and bronchiectasis or after rupture of an empyema into a bronchus

Pathology—Any material reaching the air passages in this manner is certain to be laden with infective micro organisms which may induce bronchitis and broncho-pneumonia Since pyogenic organisms are often present suppuration is frequent and single or multiple abscesses result, or even gangrene If the pleura becomes involved empyema may develop

Symptoms—These are in general similar to those of secondary broncho pneumonia and are superadded to those of the primary condition There is generally high temperature, sometimes with rigors cough and expectoration which is occasionally offensive It may be mixed with food material and with blood The physical signs are those of bronchitis and widespread broncho pneumonia

Complications and Sequelæ—These are somewhat similar to those of other inhaled foreign bodies and comprise abscess gangrene and empyema

Course—The course is often short, owing to the severity of the process and the gravity of the primary cause In the comparatively rare cases that recover, the course may be severe and protracted

Prognosis—From the nature of the primary condition and the intensity of the resulting broncho pneumonia this is usually grave

Treatment—Prophylactic.—The utmost care should be paid to the toilet of the mouth and pharynx in disease of or operations upon these parts In paralysed or unconscious patients it may be necessary to resort to nasal feeding In hæmoptysis or bronchiectasis the patient should lie rather on the affected side

In most instances the general treatment is similar to that of broncho pneumonia Postural drainage should be given

TUBERCULOUS BRONCHO PNEUMONIA

This constitutes one form of pulmonary tuberculosis (see Acute Caseous Tuberculosis p 1019)

PNEUMONITIS

Pneumonitis is a term sometimes used as a general term for inflammatory conditions of the lung It has some convenience in describing the inflammatory changes which are found in direct spread from a suppurative bronchiectasis or in association with a neoplasm of the lung which are neither broncho pneumonia nor lobar

DISEASES OF THE PLEURA

PLEURISY

Pleurisy or pleuritis is an inflammation of the pleural membrane covering the lung or of its parietal reflexions

An ætiological classification, based on the bacteriological findings would be the most satisfactory one, but is at present impracticable chiefly owing to the difficulty of establishing the bacteria concerned in many cases The classification usually adopted depends upon the effects produced If the process leads only to fibrinous deposit it is described as *dry pleurisy* If in addition much serous fluid is poured out the condition of *pleurisy with effusion* results, while if pus is formed the affection is described as *purulent pleurisy* or *empyema*

It is however important to recognise that although such a classification is convenient from a clinical standpoint the three conditions are in reality only stages or degrees in the pleural response to irritative or noxious agents The form occurring in any given case depends upon the nature of the cause the extent of the infection and the degree of resistance possessed by the individual affected Further pleural inflammations may be primary or secondary to local disease or to blood infection and they may be acute or chronic in course

A ACUTE DRY PLEURISY (ACUTE FIBRINOUS OR PLASTIC PLEURISY)

Ætiology—This affection has been described as primary and secondary It is doubtful if such a condition as primary pleurisy exists and it is wise to regard it as secondary to some pulmonary condition At all events the alleged predisposing effects of exposure to cold and wet probably play no part other than by reducing the general resistance and precipitating pulmonary disease

Dry pleurisy secondary to pulmonary disease—Dry pleurisy is a frequent complication or concomitant of many diseases of the lungs notably of pulmonary tuberculosis in any form It is almost invariably present in lobar pneumonia It occurs in association with pulmonary collapse interstitial pulmonary fibrosis bronchiectasis abscess gangrene infarcts and new growths of the lung Injuries of the chest wall disease of the ribs chronic nephritis septicæmia or pyæmia may all be complicated by acute dry pleurisy

Pathology—The inflamed area is often localised but the process may be wide spread or even involve the whole pleural surface Either the visceral or parietal layer may be first affected but as a rule both become involved There is at first hyperæmia with exudation of serum into the subpleural connective tissue The pleura then appears slightly dull or matt instead of shiny Further exudation leads to the deposit of fibrin on the roughened pleural surfaces in the form of a thin false membrane which often presents a rough or even shaggy appearance This membrane consists of fibrin entangling leucocytes a few red blood corpuscles and desquamated endothelial cells

During the process of resolution localised adhesions commonly form but this is not invariable and a patch of thickening without adhesion may be the ultimate result.

Symptoms—The onset is usually sudden with acute pain in the side often described by the patient as a stitch Occasionally a sense of malaise may precede the development of the pain by a few hours or even days but this is not the rule The pain is aggravated by deep inspiration by coughing or even by movement It is often very severe sometimes agonising and the increase of pain, which sometimes

comes as a result of an involuntary cough on deep inspiration is often described as if a knife was being driven into the chest It makes the patient catch his breath or cry out, and he often claps his hand to his ribs *in an involuntary effort to prevent* the movement of his chest wall Cough is generally an early symptom and it is characteristically short dry ineffective and distressing The temperature is usually raised, but, as a rule only to 100° or 101° F and some cases are practically apyrexial

The decubitus is variable The patient may lie on the affected side, but in some cases this aggravates the pain, and it is more comfortable to lie on the back or slightly turned towards the sound side There is diminished movement on the affected side and breathing may be rapid although not dyspnœic On palpation, vocal fremitus is unaffected, but local tenderness of the skin or muscles is sometimes found and occasionally a friction fremitus may be found although this is likely only in the stage of recovery when the pain has almost disappeared The breath sounds are generally unaltered, but they may be short or jerky in the neighbourhood of the lesion The sign of dry pleurisy is the friction rub The characteristics of these rubs depend on the stage of the inflammation and extent of the area involved The most painful rubs are often nearly inaudible because the patient's respiration is inhibited at the time of contact All that may be heard is a sound like a single localised râle which can only be recognised by its tendency to remain in the same place and to coincide with the *catch in the patient s breath as he feels the pain* At other times the rub sounds like a series of superficial dry crepitations As the friction rub becomes less painful it becomes more like creaking or rubbing leather or like the sound of a foot step on crisp crunchy snow The louder the rub the less the pain as a rule The friction sounds may be quite localised or very widespread and they may not be present with every respiration In the acute stage it is inadvisable to ask the patient to take a deep breath or, worse still to cough in order to produce the sound The voice sounds are not altered

Complications and Sequelæ—Dry pleurisy may proceed to effusion but in most cases results in the formation of pleural adhesions The most common sequel is pulmonary tuberculosis sometimes after an interval of years the explanation being *that the original pleurisy is frequently tuberculous* Aching pain in the side with some dyspnœa may be a temporary sequel of dry pleurisy

Diagnosis—The differentiation of dry pleurisy from the other causes of pain produced in, or referred to the chest wall is not always easy and requires careful observation of the case The distinction is important since an erroneous diagnosis of pleurisy may arouse a suspicion of tuberculosis in subsequent febrile diseases The term pleurodynia has been used to include fibrositis of the intercostal muscles and membranes and intercostal neuralgia The term should be avoided since it has a sound full of pomp, signifying, most often ignorance The terms it comprises are themselves suspect for the same reason

It is wise to treat any chest pain which has the characteristics of pleurisy as being pleurisy until it is proved otherwise It is, however quite true that inflammatory or traumatic changes in intercostal muscles may produce pain on respiration rather similar to the pain of pleurisy Inflammation of the intercostal nerves does also occur, but pain and tenderness tends to follow the distribution of the intercostal nerve or its anterior or posterior branches and sometimes when there is infection of the posterior ganglions it is followed by herpes zoster Other conditions inducing pain referred to the chest wall are tumours or aneurysm pressing on the intercostal nerves malignant disease of the spinal cord or of its membranes and caries of the vertebræ Where the pain lasts more than a few days, and no *friction is heard* these conditions should be borne in mind

Bornholm disease is an epidemic disease which causes acute pain of a pleuritic nature Usually the pain appears to be in the muscles of the chest wall but in some

cases pleural rubs have been described In the absence of an epidemic an isolated diagnosis of Bornholm disease should be made with reserve or it may become as unsatisfactory as the diagnosis of pleurodynia

Occasionally adventitious sounds of extra pleural origin may give rise to some difficulty Contraction of the muscles of the chest may cause a muscular ' susurrus grating sounds may be produced in the shoulder joint or in the fascial planes of the back muscles The origin of these sounds can usually be determined by causing the patient to cease breathing while carrying out movements of the shoulder or back muscles Occasionally true friction sounds may have a cardiac rhythm as well as a respiratory one when the area of pleura involved is near the pericardium It is then referred to as pleuro pericardial friction

Having established the evidence of dry pleurisy a careful search should be made for the primary condition Pulmonary tuberculosis pneumonia bronchiectasis and the other causes mentioned above should be considered and excluded

Course —The temperature and pain may subside in 2 or 3 days and convalescence may be rapid if effusion does not occur Occasionally the pain persists off and on for a few weeks but these cases are usually tuberculous and terminate in effusion

Prognosis —Depends entirely on the primary condition of the lung or the disease of which it is a complication

Treatment —The patient should be kept in bed no matter how mild the attack The diet will depend on the general condition and appetite of the patient The pain can often be relieved by strapping the affected side Strips of adhesive plaster are moulded to the chest wall about 2 in from the vertebræ on the sound side of the chest The patient is asked to breathe out and while in this position the strapping (nicked to make it lie flat) is stretched round the affected side and moulded over the sternum on to the sound side again The application should be from below upward and properly applied one or two strips will often be enough to relieve the pain They should be removed as soon as possible to prevent irritation of the skin If the strapping is ineffective and it is certain that it has been properly applied it should be removed

If the pain is intense an injection of gr $\frac{1}{6}$ or $\frac{1}{4}$ of morphine should be given and a small injection of morphine or heroin is often the best way to start any treatment since the patient is often tired and terrified Local applications to the chest such as capsicum ointment or capsicum tissue are of little value but a large kaolin poultice if well made does often give some relief and many patients derive comfort from them

Pain however severe can usually be controlled by sedatives and strapping but an artificial pneumothorax has been induced in cases where these resources failed and the pain has been especially excruciating Such occasions must be extremely rare and the operation under such conditions might produce empyema A linctus should be prescribed for the cough that often accompanies pleurisy and a sedative given at night

Convalescence is usually rapid, but the patient should not be allowed to resume work until fully restored to health and if a tuberculous origin is suspected prolonged treatment on sanatorium lines should be advised

Certain localisations of dry pleurisy require separate notice These are the diaphragmatic and interlobar forms

DIAPHRAGMATIC ACUTE DRY PLEURISY

Ætiology —This affection may occur under conditions similar to those causing dry pleurisy in other parts not infrequently it is secondary to pathological changes in the abdomen Thus hepatic cirrhosis perihepatitis perisplenitis hepatic abscess perinephric suppuration or peritonitis may lead to a spread of infection through the

diaphragm to the adjacent pleura It may also occur as a localised variety of secondary dry pleurisy, when the primary lesion is situated near the base of the lungs

Symptoms —Pain is usually very severe and may be referred to the shoulder or to the abdomen The former is caused by nociceptive impulses ascending the phrenic nerve to its origin in the third to the fifth cervical segments of the spinal cord leading to pain and hyperæsthesia referred to the cutaneous area of distribution of the fourth cervical root, at the summit of the shoulder The abdominal pain is in the epigastric and hypochondriac regions, and in addition there is a localised tender spot known as the " bouton diaphragmatique ' of Guéneau de Mussy This is situated in the subcostal plane, about 2 in from the mid line The diaphragm is nearly motionless on the affected side, and there is often some rigidity of the corresponding upper abdominal muscles Hiccough may be a noticeable and troublesome symptom The diaphragm, being nearly fixed in the inspiratory position may cause a slight downward displacement of the liver if the pleurisy is on the right side A pleural friction rub is rarely heard, the only abnormal signs commonly present being diminution of air entry and possibly slight dullness over the corresponding lower lobe of the lung

Diagnosis —This is often difficult, owing to the fact that the severity of the symptoms and their localisation frequently suggest the occurrence of some acute abdominal catastrophe such as perforation of a hollow viscus The abdomen should be most carefully examined in every case The history, the collapsed state of the patient and the evidence of free gas in the peritoneal cavity in perforation may assist in distinguishing between these conditions The symptoms however are not by any means always as severe as is suggested by the foregoing

Often this form of pleurisy can only be differentiated from ordinary pleurisy by the fact that the pain is made especially severe by any involuntary movement affecting the diaphragm such as laughing yawning, sneezing or coughing when the pain is like a knife thrust in the upper abdomen

Treatment —This is similar to that of simple dry pleurisy elsewhere save that morphine should be withheld until the diagnosis is conclusively established

INTERLOBAR DRY PLEURISY

Just as inflammation may be limited to the diaphragmatic portion of the pleura, so the membrane in the cleft between two lobes of the lung may be alone affected This does not give rise to definite symptoms and signs by which it can be diagnosed during life though its effects are not infrequently seen in radiograph films It is frequently discovered on necropsy, but is generally secondary to pulmonary tuberculosis or pneumonia and there is usually evidence of pleurisy elsewhere It only assumes clinical importance when followed by effusion and this condition is considered later

B CHRONIC DRY PLEURISY

Under this heading a variety of conditions are included Strictly, it should be restricted to those rare cases probably usually tuberculous in origin, in which the signs of dry pleurisy persist for long periods or recur at frequent intervals In such cases coarse dry friction may be heard over large areas of one lung often with little or no accompanying pain

Pleural adhesion and thickening are usually included in the group of chronic dry pleurisies There may be no symptoms or, at most slight dyspnœa on exertion with aching or pain on straining or on lifting weights Signs suggesting adhesion are local flattening and limitation of movement of the chest wall Litten s sign is also absent or diminished when the adhesion is basic, that is the shadow cast by the movement of the diaphragm best seen in the region of the seventh and eighth ribs in the anterior and mid axillary lines is not present or is much restricted The vocal

fremitus may be diminished and the percussion note impaired The breath sounds are often slightly weaker and the voice sounds may be diminished over the area where the thickening or adhesion exists

Chronic diaphragmatic pleurisy or adhesion may give rise to a group of symptoms simulating chronic gastric ulcer There is pain in the hypochondrium extending through to the back and aggravated by food Radiographic examination may be of value in demonstrating limitation of movement of one cupola of the diaphragm together with an angularity due to alteration of its normal contour Investigation of the gastric functions may also prove of value in diagnosis

The treatment of chronic dry pleurisy is mainly symptomatic.

C PLEURISY WITH EFFUSION

Many cases of pleurisy, possibly the majority, proceed to effusion The effusion is usually serous in character, but may be hæmorrhagic Inflammatory effusions must be distinguished from passive transudates which will be considered separately under the heading of hydrothorax

SERO FIBRINOUS PLEURISY

Ætiology —This is in the main identical with that of dry pleurisy of which it is, in effect a later stage It has now been established that the majority of cases of sero fibrinous pleurisy are due to the tubercle bacillus The evidence on which this conclusion has been arrived at is—(1) the subsequent history of the cases shows that a considerable proportion develop active lung signs within 5 years (2) the cytological and bacteriological examination of the exudate (3) post mortem examination of fatal cases (4) the results of tuberculin reactions

Other conditions which may give rise to serous effusions are lobar and lobular pneumonia pulmonary infarcts and new growth It may also occur in the course of generalised infections such as the enteric group acute rheumatism and septicæmia due to streptococci or staphylococci In most of these conditions the exudate often becomes purulent Inflammatory serous effusion may also occur as a complication of severe anæmias leukæmia chronic nephritis injury to the chest wall and inflammatory conditions below the diaphragm or in the pericardium It is also a common feature of polyorrhomeningitis

Pathology.—The affection commences with dry pleurisy spreading over the visceral and parietal pleura the fibrinous exudate soon forming a thick rough layer on the surface Further exudation of fluid occurs and accumulates in the pleural cavity the lung collapsing *pari passu* to accommodate it Owing to the hilar attachment of the lung it retracts upwards and inwards allowing the fluid to accumulate at the bases and in the axillary region where it reaches its highest level unless previously existing adhesions prevent it The lung retracts in this way owing to its elasticity until the pleural negative pressure is completely abolished In like manner the mediastinal contents including the heart, are displaced away from the affected side If fluid continues to be effused after the lung has retracted to the full extent and after the negative pressure has become abolished, a positive pressure is produced The lung is now compressed and the diaphragm with the liver and spleen are pushed down while the mediastinal structures are now displaced further towards the sound side In long standing cases the lung may undergo the change known as carnification as the result of the compression apneumatosis The lung appears dark red or slaty grey in colour, is firm airless and heavier than water If old adhesions are present, the effused fluid may be loculated and the collapse of the lung may be only partial

If there is much positive pressure collateral hyperæmia of the sound lung may result and progress to œdema The fluid in the pleural cavity is pale and clear it

often coagulates after withdrawal Its characters are further described on p 1070 The quantity may amount to as much as 5 or 6 pints

Symptoms —The onset is usually similar to that of dry pleurisy, but the constitutional symptoms are often more marked There may be an initial rigor but as a rule pain and dry cough are the earliest symptoms The fever is of moderate degree, although it may reach 103° F or more When effusion develops the pain is often relieved owing to the separation of the inflamed pleural surfaces If a large quantity of fluid is poured out rapidly, distress of another kind becomes apparent namely dyspnœa caused by the mechanical effects of the fluid, collapsing the lung and displacing the mediastinum In more slowly developing effusions there may be little or no dyspnœa, except on exertion Expectoration is not common unless there is coexisting pulmonary disease, or unless œdema of the sound lung develops

The patient often lies on the affected side or may be propped up in bed Cyanosis is not a marked feature even in large effusions, unless there is collateral hyperæmia of the sound side There is generally some prominence on the side of the effusion but the intercostal spaces are rarely bulged Movement is restricted or absent in the lower part of the chest on the affected side although with a moderate effusion the apical region may still expand The cardiac pulsations may be seen in an abnormal position, the impulse being displaced away from the side of the fluid In left sided effusions the pulsation may be most marked in the fourth space on the right side as far out as the nipple line On palpation the position of the impulse should be verified, and then the amount of chest movement and the character of the vocal fremitus determined The latter is diminished or completely absent over an effusion of moderate or large size, although it may be obtained over the area where the collapsed or relaxed lung is in contact with the chest wall The percussion note over the fluid is one of stony dullness and the sense of resistance is greatly increased The exact limits of this area of dullness should be determined with the patient sitting up and recumbent With moderate effusions the upper border of the dull area follows a curved line with the convexity uppermost known as the S shaped curve of Ellis or Damoiseau's line This is lowest at the back near the spine and reaches its summit in the mid axilla it then slopes downwards as it passes anteriorly towards the sternum In large effusions the dullness may extend up to the level of the clavicle and reach across the mid line of the sternum, moreover in left sided effusions it blends with the cardiac dullness, and the area of gastric resonance known as Traube s space may be encroached on or obliterated The relaxed lung above the effusion in front often yields a skodiac note which becomes dull if the quantity of fluid increases At the back there is a triangular area of impaired resonance or relative dullness above the stony dull area of fluid This is known as Garland s triangle It also corresponds with the relaxed or collapsed lung If the patient is examined while sitting upright there is often found at the base on the sound side opposite the effusion, a small area of dullness known as Grocco s triangle The base of this triangle extends outwards from the vertebral column along the lower margin of the lung for one to three inches the vertical side extends upwards at a right angle to the base, alongside the spinal column to about the highest level of the effusion, the hypotenuse joins these two lines This paravertebral dull area is caused by the bulge of the fluid forming the effusion Elsewhere over the sound lung the note may be slightly hyper resonant The area of deep cardiac dullness should be carefully marked out In left sided effusions it is displaced to the right and extends beyond the sternum in the third and fourth spaces even to the nipple or beyond it In right sided effusions, the displacement may be very obvious the left margin of the dullness extending as far out as the left mid axillary line The auscultatory signs are very variable, and much less characteristic than those obtained by palpation and percussion In some cases the breath-sounds over the dull area are distant and weak or even absent in others they are loud and bronchial or tubular This inconstancy probably depends upon

the extent of pulmonary collapse and the degree of patency of the bronchi With marked collapse and patent bronchi bronchial breathing is heard with partial collapse and obstructed bronchi the breath sounds are almost or quite abolished As a rule no adventitious sounds are heard but râles may be audible in the lung above the effusion Conduction of spoken voice is diminished or abolished but towards the upper part of the effusion and just above it the sound produced is heard distantly and with a peculiar nasal or bleating twang a condition known as ægophony The breath sounds heard under the clavicle over the relaxed lung above the effusion are frequently harsh or puerile In the contralateral lung the breath sounds may be vesicular or exaggerated and in cases of large effusions where there is marked circulatory obstruction there are frequently signs of congestion or œdema at the base Similarly pressure on the descending thoracic aorta may cause lowering of the blood pressure in the leg as compared with that in the arm (O K Williamson) There may be a systolic murmur over the cardiac region (displacement murmur) The abdomen should be examined to determine any downward displacement of the liver or spleen The blood count in sero fibrinous pleurisy rarely shows any leucocytosis apart from complications

Complications and Sequelæ—Acute œdema with albuminous expectoration is rare but is a dangerous condition unless treatment is prompt Permanent collapse and carnification of the lung may remain after absorption in prolonged cases and may progress to diffuse interstitial fibrosis More commonly some degree of pleural thickening and adhesion persists and expansion of the lower lobe may never be completely restored Sero fibrinous effusion due to tuberculosis rarely becomes purulent but this sequence is common in other forms Tracking of the fluid externally through the chest wall and rupture through the lung occur but rarely An infrequent complication is hemiplegia probably due to an embolus derived from a thrombus originating in a pulmonary vein Miliary tuberculosis occasionally follows rapidly on an effusion more commonly active tuberculosis of the lungs occurs after a lapse of some years

Diagnosis—The recognition of the presence of fluid in the pleural cavity is generally easy but with small or localised effusions it may be difficult The most valuable signs are the displacement of the heart the absence of vocal fremitus and the stony resistant dullness The auscultatory signs are of less value and may even be misleading The chief conditions which may simulate effusion are fibroid lung *with thickened pleura and bronchiectasis pneumonia particularly the massive form* malignant disease of the lung pleura or mediastinum massive collapse a large pericardial effusion and an aneurysm pressing on one or other main bronchus Subphrenic abscess may also give rise to difficulty (see Empyema) Fibroid disease can usually be recognised since there is generally flattening and sinking in of the affected side instead of bulging The heart if displaced is drawn towards instead of away from the affected side vocal fremitus is present although possibly diminished and the dullness is rarely of the stony character obtained over fluid The breath sounds *may be weak or bronchial and if bronchiectasis is also present the characteristically* variable signs of that condition should be helpful in diagnosis In massive pneumonia the differentiation may be difficult since breath sounds and voice sounds are sometimes completely absent if the bronchi are also occluded but the position of the cardiac impulse is generally of decisive importance In malignant disease and aneurysm careful observation should afford diagnostic indications such as glandular enlargement or abnormal pulsation and in both instances the radiograph may establish the diagnosis Malignant disease of the pleura may first show itself as a pleural effusion the tendency to recur after tapping the presence of blood in the effusion and the onset of emaciation may help to suggest the cause In massive collapse there is as a rule but little difficulty owing to the displacement of the cardiac impulse to the affected side In pericardial effusion the shape of *the cardiac dullness* may be sugges

tive, and the dislocation of the impulse may indicate the real condition, moreover the dullness over the lung behind is rarely of extreme degree unless pleural effusion coexists Radiographic examination is always desirable The shadow of fluid is generally dense, but does not obscure the rib shadows completely The upper level tends to be curved and shifts to some extent with the patient It merges into the shadow of the collapsed lung above The diaphragm is immobile on the affected side A further aid to diagnosis consists in exploratory puncture which has the advantage of establishing the nature of the fluid as well as its presence The technique of puncture is similar to that of paracentesis described below save that a hypodermic syringe with a Record 1 or 2 needle is often quite sufficient for diagnostic purposes Preliminary local anæsthesia by procaine (Novocain) or some similar preparation, should be employed in every case The same syringe and needle used for anæsthesia may also be used for the diagnostic puncture Serous pleural fluid of inflammatory origin varies in colour from pale greenish-yellow to brown The specific gravity is usually 1 018 or over Protein is present as serum albumin serum globulin and fibrinogen, the total quantity being as a rule over 4 per cent The fluid generally clots spontaneously after withdrawal The cytology of the fluid is varied showing lymphocytes, polymorphonuclear cells, erythrocytes and altered endothelial cells in varying proportions A marked preponderance of lymphocytes is very suggestive of a tuberculous origin while the presence of large numbers of polymorphonuclear cells is usually an indication of some other infection, generally by a pyogenic organism In rare cases large numbers of eosinophils have been found The origin of these cases of so called eosinophil pleurisy is at present doubtful Cultural examination of tuberculous fluid usually proves sterile unless Loewenstein s or Dubos medium is used, but in fluid from other causes the infecting organism can often be grown To establish the tuberculous nature of a pleural fluid, inoculation of 15 ml of the fluid into a guinea pig may be tried The methods of differentiation of an inflammatory exudate from a passive transudate are given on p 1076

Course—In effusions of moderate size the temperature usually subsides in from 7 to 10 days, and spontaneous absorption is complete in 2 3 or 4 weeks In large effusions reaching up to the second rib or higher, the course may be less favourable The fever may persist even for weeks and absorption of the fluid may be slow or wanting entirely Aspiration may accelerate the resolution, and usually only one tapping is necessary, the fluid left behind being absorbed rapidly In rare cases fluid reaccumulates quickly after repeated tappings and a so called inexhaustible effusion occurs In some such patients fluid may remain in the pleura for the rest of life

Prognosis—The immediate prognosis is good, although with large effusions of 4 pints or more, sudden death sometimes occurs from acute œdema of the lungs cardiac failure or embolism The ultimate result depends on the cause In non tuberculous effusions recovery may be complete, save for pleural adhesion or they may progress to empyema In tuberculous effusions arrest may remain complete but, as already stated a considerable proportion of the cases develop pulmonary disease after years

Treatment—Paracentesis can be carried out in various ways The simplest method is that of siphonage a long rubber tube filled with sterile saline solution is attached to a trocar and cannula which are passed into the pleural cavity and the fluid is siphoned into a receptacle at a lower level This method has the great advantage that the degree of suction employed is under control and the lungs expand gradually as the fluid is withdrawn When this method works it is very effective but it sometimes fails for various reasons A double acting syringe or a syringe with a two way tap is more often used and some still use Potain s apparatus which is effective if the corks and connections are in good condition

In performing aspiration the patient should sit up in bed or lie slightly turned

on to the unaffected side The skin should then be prepared as for an operation and the whole procedure should be carried out as a sterile operation The skin and muscles should be well infiltrated down to the pleura with procaine 2 per cent and the needle used for the anæsthetic should be pushed into the pleural space to make certain that anæsthesia is complete and to confirm the position of the fluid A sharp needle or a small trocar and cannula should be pushed into the pleural space just above a rib *in order to avoid the intercostal artery on the under surface of the rib* above The site chosen depends on the position of the fluid but the most convenient ones are the sixth space in the mid axilla the seventh space in the posterior axillary line or the eighth space just below the angle of the scapula Aspiration should be stopped if cough occurs or the patient complains of any general malaise or discomfort Aspiration is exhausting to the patient so should not be too prolonged Removal of 1 to 2 pints is all that it is safe to remove at one aspiration and removal of more and too rapid removal of as much may produce œdema of the lung and albuminous expectoration by affecting the pulmonary circulation Removal of only part of an effusion sometimes seems to accelerate the absorption of the whole probably by the chain effect of increasing mobility One of the risks of paracentesis is said to be sudden death from pleural shock Sudden death does very occasionally occur but is probably due to air embolism a risk inseparable from the use of a hollow needle Other risks are also due to faulty technique and comprise entrance of air into the pleural cavity from ill fitting needles or wrong connections or from puncture of the lung

The operator must always keep in mind the danger of infecting the pleural cavity through a failure in sterility

Exploratory puncture is advisable to permit the examination of the fluid Opinions differ somewhat as to the indications for paracentesis which however is nowadays performed earlier and more frequently than was formerly the case It is unnecessary in cases in which absorption of the fluid is apparent within 10 days The following conditions may be considered to suggest its employment (1) if the effusion is large and causing positive pressure as shown by dullness up to the clavicle marked dyspnœa downward *displacement of the liver or spleen and collateral hyperæmia of the sound* lung (2) if absorption is slow the fluid remaining at the same level for a fortnight or more (3) if acute œdema with albuminous expectoration occurs (4) in cases of bilateral effusion with increasing dyspnœa the side with the larger effusion may be aspirated (5) if the effusion is accompanied by persisting high temperature and constitutional symptoms

The old cliche that the pleural effusion is Nature s splint and other old saws have been responsible for a great deal of unnecessary permanent disability as a result of not aspirating large effusions Generally speaking large effusions should be aspirated early and the aspiration repeated if necessary Often however the aspiration of a moderate amount of fluid facilitates the reabsorption of the rest through increasing the momentum of the pulmonary movements There are, however still many different opinions on the subject of whether or not to aspirate a tuberculous effusion It has long been a common custom to leave the effusion unaspirated on the ground that it acts as a form of collapse therapy There is no evidence that this is true and it is certain that this belief leads to unnecessary discomfort and avoidable disability If collapse therapy is necessary in these cases air replacement would be a more logical and effective remedy

General Management —Patients with large effusions should be nursed propped up on pillows they should be discouraged from sudden lateral alteration in position as the sudden displacement of the mediastinum may cause distress and cardiac embarrassment The patient should be told that he will be away from work for not less than 6 months For about the first 3 months he should be kept in bed although if the fluid has reabsorbed and the temperature and the sedimentation rate have been normal for 3 weeks he may get up by degrees towards the end of the period He

should spend the next 3 months in the most healthy circumstances possible observing daily rest and early hours During all this time he must be under strict radiological control which will be necessary for at least 5 years The radiographs should be monthly at first then 3 monthly and eventually at 6 months intervals The convalescence of some patients will be delayed by persistence of temperature or fluid or both

Since statistics show that between 20 to 30 per cent of pleural effusions are followed by pulmonary tuberculosis inside 5 years and since streptomycin has been found to be most effective in recent presumably vascular lesions it appears logical to treat these patients with it during their period of rest Streptomycin in daily doses of 1 g should be given in two courses of 21 doses, separated by 14 days interval To diminish the likelihood of producing streptomycin resistance isoniazid in 100 mg doses twice daily should be given at the same time as the streptomycin

ANOMALOUS PLEURAL EFFUSIONS

Two unusual forms of pleural effusion require brief mention—they are encysted interlobar and encysted diaphragmatic sero fibrinous pleurisy The former can only be recognised by radiographic examination followed by exploratory puncture Encysted diaphragmatic sero fibrinous pleurisy is rare, but a case has been erroneously recorded as acute serous mediastinitis This condition is simply one of pleural effusion localised to the space between the mediastinal pleura, the diaphragm and the lung Both of these conditions if diagnosed, should be treated on general principles The effusion may absorb spontaneously but if not, aspiration may be necessary

PURULENT PLEURISY (EMPYEMA)

In this condition the pleural exudate becomes purulent The fluid may be turbid and the presence of pus be apparent only on microscopical examination, or it may consist of typical pus

Ætiology —Predisposing Causes —Empyema is common in children under 10 years of age, and the younger the child the greater the probability that any effusion will be purulent In adults it is commonest between the ages of 20 and 40 years, probably owing to the heavy incidence of pneumonia in this age period Purulent pleurisy is but rarely primary except in the form due to the pneumococcus It is most commonly due to extension from the lungs especially from lobar pneumonia and from broncho pneumonia Other pulmonary causes are tuberculosis, bronchiectasis, abscess gangrene new growth or septic infarcts in infective endocarditis It may develop in association with mediastinal lesions, such as suppurating glands ulcerating carcinoma of the œsophagus or from suppuration in the neck tracking downwards Infection of the pleura may occur through the chest wall as a result of gunshot wounds stabs, fractured ribs and faulty technique in aspiration of a serous effusion The primary source of pleural infection may be in the abdomen, the organisms passing through the diaphragm from a perinephric subphrenic or hepatic abscess, or from localised or generalised peritonitis consequent on rupture of a gastric or duodenal ulcer The involvement of the pleura may take place through the blood in septicæmia suppurating gunshot wounds compound fracture of the femur and in otitis media with lateral sinus thrombosis

Empyema may develop during the course of many of the acute specific fevers such as scarlet fever variola measles and the enteric group, but since in these conditions it is usually secondary to broncho pneumonia it belongs strictly to the pulmonary group

EXCITING CAUSES —The organisms most frequently found in purulent effusions are the pneumococcus and the streptococcus the former accounting for more than

half of the cases Occasionally the pus proves to be sterile on culture such cases are generally the result of the tubercle bacillus or of a pneumococcus which has died out Other organisms less commonly found are staphylococci *H influenzæ Salm typhi Bact coli* and Friedlander s bacillus Streptothrix organisms are occasionally found (see Actinomycosis) also various saprophytes and anaerobic organisms especially in fetid empyema

Pathology—The initial stages are similar to those of dry and sero fibrinous pleurisy but when the effusion occurs it proves to be rich in leucocytes undergoing disintegration and to contain the infecting organism It varies from a slightly turbid semi translucent fluid to typical thick opaque creamy pus Its colour ranges from pale amber to green or greenish grey It may be odourless or extremely offensive In cases secondary to gangrene it may be thin and horribly fetid while in pneumococcal cases it may be curdy and of slightly sweetish odour The pleura is covered with a more or less thick layer of sodden fibrinous exudate In cases due to the pneumococcus this false membrane may be very thick Adhesions form quickly leading to encystment or loculation of the pus Such adhesions also prevent the lung from expanding after evacuation of the pus with the result that the lung becomes carnified and interstitial fibrosis results There is usually some enlargement of the bronchial glands In long standing cases there may be lardaceous disease of the liver, spleen kidneys and intestines

Symptoms—Since empyema usually develops in the course of or as a sequel of some other disease its symptoms are often masked by those of the primary disease and may easily be overlooked In primary cases due to the pneumococcus the onset may be like that of pneumonia in the more common secondary cases a rise of temperature and increase of signs develop after the crisis In general it may be stated that the symptoms are similar to those of sero fibrinous pleurisy but more severe There is more malaise and the patient may appear profoundly ill with rigors sweats and dyspnœa The temperature ranges higher up to 103 F or more and may be of septic type with marked daily remissions but some cases are almost if not completely apyrexial The signs are usually exactly similar to those of sero fibrinous effusion but in some instances special features may be noticed In neglected or prolonged cases wasting pallor and cachexia become marked The intercostal spaces may be found to bulge and œdema of the chest wall is sometimes apparent The pus may track through an intercostal space generally the fifth near the nipple producing a fluctuating swelling known as a pointing empyema or *empyema necessitatis* This may infiltrate the skin and simulate a superficial abscess The swelling so induced may pulsate especially if it be on the left side—a condition known as pulsating empyema Pulsation communicated to the chest wall may also be observed in some large left sided purulent effusions without local swelling The displacement of the liver or spleen may be greater than with serous effusions probably owing to the higher specific gravity of the pus which is usually 1 030 or more and to the associated inflammation of the diaphragm In fetid empyema the breath and sputum may be offensive even before rupture into a bronchus occurs Clubbing of the fingers and toes occurs in empyema of long standing but may develop in a few weeks Blood examination reveals a moderate leucocytosis in the majority of cases Counts of 15 000 leucocytes per cubic millimetre are usual and in some instances figures up to 100 000 per cubic millimetre are obtained

Complications and Sequelæ—In neglected or untreated empyema the pus may track and become discharged in various directions The commonest is rupture through the visceral pleura into the lung and discharge through a bronchus This may lead to sudden death from suffocation on the other hand in small empyemata spontaneous cure may follow this evacuation of the pus In other instances pyo pneumothorax results and occasionally gangrene of the lung A second method of discharge is through the chest wall as an *empyema necessitatis* Perforation may

occur into the pericardium, or into the œsophagus with the formation of a pleuro œsophageal fistula The diaphragm may be perforated with the production of a sub phrenic, lumbar or psoas abscess, while in other cases general peritonitis may ensue

The pericardium or the mediastinum may become infected without perforation similarly costal periostitis may be induced After spontaneous or operative evacuation the cavity may fail to close and a chronic empyema or sinus result This is generally due to the lung being permanently collapsed and adherent and therefore failing to expand It subsequently undergoes fibrosis with development of bronchiectasis Sometimes the failure to close may be due to the nature of the infection particularly when it is due to tuberculosis or actinomycosis In other cases it may be due to a bronchial fistula or to a foreign body in the pleura Generalised infection is rare but cerebral abscess, probably of embolic origin, is not very uncommon especially in cases due to streptococci Chronic pulmonary osteoarthropathy is an occasional complication, and lardaceous disease sometimes occurs in cases of long duration Diphtheritic infection of the wound, with subsequent paralysis has been recorded after operation, more especially in cases secondary to influenzal broncho pneumonia

The sequelæ in untreated cases may be fistulæ such as pleuro bronchial pleuro œsophageal or external, and various deformities The sequelæ after operation may be a small amount of pleural thickening or if operation were delayed and re-expansion incomplete there is falling in of the chest, with flattening dropping of the shoulder and secondary scoliosis In other cases, as mentioned above, a chronic sinus may result.

Diagnosis —The diagnosis of empyema involves two distinct problems—one the recognition of the presence of fluid in the pleura which is considered under sero fibrinous pleurisy the other the demonstration of its purulent character In spite of the more severe symptoms, empyema is frequently overlooked even by physicians of experience This is partly due to the fact that its development may be insidious with signs increasing but little from day to day, and partly to its secondary character, its onset being obscured by the clinical features of the primary condition It is wise therefore to suspect its existence in any case of obscure lung signs especially those with dullness, cardiac displacement and fever, consequent on pneumonia of any variety

There are a few special difficulties as compared with sero fibrinous effusion which merit separate mention The first of these is subphrenic abscess This may lead to immobilisation of the diaphragm on one side more commonly the right, and cause collapse of the lung and even pleural effusion The difficulty is greater when the subphrenic abscess contains gas as well as pus The history the absence of displacement of the heart s impulse and radiography may all assist but the differentiation is often extremely difficult

Empyema necessitatis may simulate a tuberculous or other abscess about a rib and empyema should always be suspected in any case of local fluctuant swelling about the chest wall Pulsating empyema requires to be distinguished from aortic aneurysm the pulsation is less forcible and little if at all expansile in the former The cardiac displacement the radiograph and cautious exploratory puncture enable the nature of the condition to be recognised

In any case in which empyema is suspected three examinations may be under taken—a blood count radiographic investigation and exploratory puncture A poly morphonuclear leucocytosis of 15 000 per cubic millimetre and over a dense shadow in the radiograph obscuring the ribs together with cardiac displacement may be very suggestive while puncture may prove the presence of pus Sometimes however puncture may fail although pus is present This may be due to the pus being too thick to pass through the needle to loculation of the pus or to wrong choice of the site for puncture The latter explanation is usually the real one since quite thick pus will often pass through quite a thin needle In this case if

the other signs indicate pus repeated punctures with a larger needle under anæsthesia are called for but it is well to be prepared to proceed to operation if pus is found

Course —Apart from spontaneous cure of small empyemata by inspissation of the pus or discharge through a bronchus or through the chest wall death generally occurs in untreated cases within a month or two As in sero fibrinous pleurisy sudden death may occur Death may occur after operation from exhaustion or from cerebral abscess

Prognosis —This depends upon the primary cause the method of treatment adopted and the duration of the effusion before the operation The most favourable forms are those due to the pneumococcus which are recognised and treated at an early stage In neglected cases with profound toxæmia, with gangrene of the lung or lardaceous disease the outlook is extremely grave Empyemata due to streptococcal infection are serious unless recognised early similarly with cases of fetid empyema due to anaerobic infections Infected hæmothorax consequent on gunshot wounds of the chest is of grave prognosis The outlook is serious in cases of bilateral empyema but recovery may follow evacuation of the pus on the two sides

Treatment —The pus aspirated should be sent for cultivation and the organisms identified and examined for sensitivity to various antibiotics In the meantime as much of the pus as can be conveniently and comfortably removed should be aspirated and in the absence of more definite information as to the susceptibility of the organ isms up to 500 000 units of penicillin should be put into the pleural cavity at the end of aspiration Cultivation of the organisms may show that other antibiotics would be more appropriate if there are to be subsequent aspirations

Some cases of empyema may clear up with aspiration and antibiotics alone but it is wise to assume that operation will probably be necessary when the empyema has become localised in the chest Indications that suggest that operation might not be necessary would be that the fluid showed signs of disappearance, that the fluid had become sterile and from being purulent and thick was becoming serous and thin while the leucocytosis and temperature had subsided Neglected or missed empye- mata are rarely seen in Great Britain nowadays but the desperately ill case with a large empyema is often best treated at first by the use of a trocar and cannula and the insertion of an intercostal catheter which is led off into a drainage bottle with a water seal Controlled drainage of this sort is less exhausting to these patients than aspiration, and soon makes them fit for operation which would probably have been fatal beforehand

Before the use of antibiotics treatment consisted in the evacuation of the pus by operation as soon as the diagnosis was established in pneumococcal cases In those of streptococcal origin operation was not resorted to while the fluid was of thin sero purulent character but was postponed until it was definitely purulent Premature operation in streptococcal cases has been shown by the American Empyema Commission to be a very dangerous procedure since the fluid is not shut off by adhesions and operation may lead to open pneumothorax with flapping mediastinum At this stage the condition is described as pyothorax A preliminary aspiration is of advantage in large effusions and may be repeated in streptococcal effusions until they are ready for operation The operation consists in drainage by removal of a piece of rib subperiosteally and incision of the parietal pleura

In cases of chronic empyema or of sinus failing to close the question of some plastic operation must be considered Various forms of operation have been devised involving removal of portions of many ribs and the decortication operation of Fowler and Delorme The general condition of the patient must be carefully considered before these operations are advised

Special Varieties of Empyema —Certain special localisations of purulent pleurisy require separate consideration notably apical interlobar and diaphragmatic empyemata

Apical empyema —This condition is usually secondary to apical pneumonia less

commonly to pulmonary tuberculosis It is one variety of encysted empyema the pus being shut off from the rest of the pleural cavity by *adhesions* The symptoms and signs are not characteristic but may be suggestive There is very marked dullness below the clavicle, *not* transgressing the middle line with weak or absent breath sounds and possibly some indications of mediastinal displacement Diagnosis can as a rule be established only by the radiograph and exploratory puncture, the latter being carried out in the second space near the mid clavicular line The treatment consists in drainage by incision as near the lower limit of the effusion as possible

Interlobar empyema—Pus collecting between two of the lobes may be difficult to differentiate from pulmonary abscess, gangrene and bronchiectasis It is often not diagnosed until rupture into a bronchus draws attention to it The signs are generally most marked in the axilla or near the angle of the scapula They are often slight until rupture occurs, and even then there may be only a small area of dullness in the line of an interlobar fissure, with distant or weak bronchial breathing and a few rales The pus expectorated may be fetid, and the patient s breath may be offensive a few days before rupture occurs The condition simulates abscess of the lung and may be almost impossible to differentiate from that affection Radiographic examination gives the greatest help in the diagnosis Recent observations suggest that interlobar empyema is much less common than abscess The treatment is identical with that for pulmonary abscess

Diaphragmatic empyema—The pus is usually encysted and may be so deeply situated as to give but few signs The initial symptoms are generally severe, being those of diaphragmatic pleurisy but hiccough is often a troublesome feature When pus forms there may be marked constitutional symptoms, and obscure signs may develop, such as dullness at a point just above the base behind, with weak or distant bronchial breathing With such a history and obscure basic signs especially when they occur *after* an attack of pneumonia the use of the radiograph and of the exploring needle should not be neglected In cases not recognised and treated, rupture into a bronchus or through the diaphragm may occur The treatment is similar to that for ordinary empyema

HYDROTHORAX (DROPSY OR HYDROPS OF THE PLEURA)

Hydrothorax is the name applied to a collection of clear fluid in the pleural cavity the result of passive transudation from the capillaries

Ætiology—The commonest cause of hydrothorax is cardiac failure It occurs in acute and chronic renal disease, under conditions similar to those leading to dropsy in these affections It is sometimes found in severe *anæmias* *especially pernicious anæmia* Obstruction to the azygos veins may lead to transudation into one pleural cavity or into both This obstruction may be induced by *pressure from without* by a mediastinal or pulmonary new growth or by internal causes such as thrombosis An ovarian fibroma may be complicated by ascites and hydrothorax, a condition known as Meigs syndrome

Pathology—The pathology of hydrothorax is that of dropsy elsewhere It is produced by mechanical or chemical conditions affecting the blood flow through the capillaries, and it must be distinguished carefully from inflammatory effusion There is a difference in the composition as well as in the origin of the two kinds of pleural fluid The characters of inflammatory effusions have been described under pleurisy with effusion The fluid in hydrothorax is pale yellow in colour and the specific gravity is 1 015 to 1 010 or less It is clear and does not clot after removal There is little protein often not more than 1 per cent but transudates due to local obstruction may contain as much as 3 per cent The cellular elements are scanty although some endothelial cells may be present often united together in plaques The fluid may be definitely blood stained when it is described as hæmo hydrothorax

Hydrothorax is usually bilateral in cases due to cardiac or renal disease but in the former there is often more fluid on the right side or the fluid may be confined to that side The explanation of this is somewhat obscure It has been suggested that it is due to pre sure or traction on the vena azygos major by the enlarged right heart but according to Fetterolf and Landis a more likely explanation is pressure of the distended right auricle upon the pulmonary veins Fluid may also collect in greater quantity on the side upon which the patient lies most constantly In cases with unilateral pleural adhesion œdema of the lung may occur on that side while hydrothorax occurs upon the other

Symptoms—The symptoms of hydrothorax are generally overshadowed by those of the condition causing it but the occurrence of dyspnœa and cyanosis in any case of cardiac or renal disease should suggest careful examination of the bases of the lungs In the absence of inflammatory complications the condition is afebrile The signs are identical with those of sero fibrinous pleurisy save that no friction sounds are audible at any stage It is however more difficult to assess the signifi cance of displacement of the cardiac impulse owing to the increased size of the heart in the cases of cardiac origin

Diagnosis—This depends upon the presence of signs of fluid in the pleura in association with cardiac or renal disease with absence of fever and also upon the characters of the fluid withdrawn by puncture or aspiration Meigs syndrome is liable to be mistaken for a malignant ovarian tumour

Treatment.—Removal of the fluid may give great relief It may be necessary to repeat the operation since the fluid often reaccumulates The treatment of the primary condition should also be carried out. Mercurial diuretics are sometimes effective and may be given where there is no evidence of renal disease

HÆMORRHAGIC PLEURAL EFFUSIONS

All fluids poured out into the pleura contain a certain number of red blood corpuscles It is only when a number sufficient to give a definite red colour is present that the fluid is regarded as hæmorrhagic

For convenience of description three forms may be differentiated—(1) Hæmor rhagic pleurisy or hæmo serothorax (2) hæmo hydrothorax and (3) hæmothorax

1 Hæmorrhagic pleurisy

This is simply a pleurisy with effusion in which the exudate is blood stained

Ætiology—The usual causes are malignant disease of the lungs pleura or medi astinum and sometimes tuberculosis of the lung and pleura Hæmorrhagic pleurisy may occur in association with hepatic cirrhosis but in this case it is often the result of a terminal tuberculosis It occurs less frequently in association with blood diseases such as purpura and with the malignant or hæmorrhagic varieties of acute infectious fevers such as scarlet fever and small pox and occasionally with lobar pneumonia Sometimes in tapping a sero fibrinous effusion for the second time it is found that the fluid which was originally clear is now blood stained This is not necessarily an indication of increase in the severity of the process but may be due to injury of a blood vessel at the first operation

Symptoms—The symptoms and signs are identical with those of serous effusion and the hæmorrhagic character can only be recognised by withdrawal of the fluid An interesting point is the frequency of excess of eosinophils in these effusions Diag nosis and treatment are the same as for sero fibrinous pleurisy

2 Hæmo hydrothorax

This condition has been referred to under hydrothorax It consists simply in blood staining of a passive transudate into the pleura

3 HÆMOTHORAX

Hæmorrhage into the pleural cavity is the result of injury or disease of the vessels of the lung, mediastinum or chest wall

Ætiology—The chief causes are injury such as penetrating chest wounds or fracture of the ribs rupture of an aneurysm and erosion by new growth Experience of the traumatic group has been largely increased during the War of 1914–1918 and the War of 1939–1945 Hæmothorax was noted in about 70 per cent of chest wounds Occasionally it occurs after the spontaneous rupture of adhesions and it is a rare complication of artificial pneumothorax treatment and a less rare complication of adhesion section in pneumothorax treatment

Pathology—The effused blood generally comes from the lung vessels, less commonly from the intercostals It is 'whipped' by the movements of the heart and lungs with the result that fibrin is deposited in layers upon the diaphragmatic pleura and the parts of the visceral and parietal pleura in contact with the blood The fluid remaining in the pleura or withdrawn by aspiration is largely defibrinated and therefore does not clot unless a secondary pleurisy develops

The lower lobe of the lung on the affected side becomes collapsed and eventually carnified unless absorption occurs or unless the blood is aspirated The upper lobe may show some compensatory emphysema and adhesions may form in the pleura separating it from the hæmothorax below When secondary infections of the bronchi or lungs occur, such as bronchitis or broncho pneumonia the collapsed lower lobe is not affected

Symptoms—The symptoms of hæmorrhage into the pleura from medical causes, such as rupture of an aneurysm or erosion of a large vessel are collapse and rapid death When due to disease or injury of an intercostal vessel, they may be insidious and slowly ingravescent until dyspnœa restlessness and the other indications of internal hæmorrhage develop When due to injury similar symptoms occur but may be masked or overshadowed by the shock, hæmoptysis and cough induced by the wound of the lung or chest wall The signs are those of pleural effusion, but in traumatic cases certain special features may be mentioned There is a great tendency to retraction of the chest wall on the affected side and the cupola of the diaphragm on this side is displaced upwards Irritation of the diaphragmatic pleura by the presence of blood may cause rigidity of the upper abdomen which sometimes gives rise to an erroneous diagnosis of intestinal perforation Vocal fremitus is usually diminished or absent Breath sounds will usually be absent but bronchial breathing may be heard and in these cases the voice conduction is also increased

Complications and Sequelæ—The most serious complication is infection of the effusion This is generally due to organisms introduced at the time of the wound either by the missile or by portions of the clothing or skin carried in with it Aerobic organisms such as a streptococcus or anaerobic ones as the *Clostridium Welchii* or *Cl sporogenes* may be present A hæmo pneumothorax may develop the gas entering the pleural cavity from the wound in the lung or through the chest wall Gas may also be formed by gas producing infecting organisms in the effusion Massive collapse may occur in the contralateral lung or other complications may arise such as bronchitis broncho pneumonia lobar pneumonia or œdema of the lungs If the effusion is small and not infected there are usually no permanent after effects In severe cases sequelæ similar to those of sero fibrinous pleurisy and empyema may result

Diagnosis—Hæmothorax should be suspected when basic dullness develops shortly after a gunshot wound of the chest The mistake that is most likely to be made in such cases is to confuse hæmothorax with lobar pneumonia The cardiac displacement and the diminution of vocal fremitus over the dull area are the most valuable diagnostic signs An active lobar collapse is distinguished by the fact that

the heart is displaced towards the affected side Radiography affords valuable confirmatory evidence in most cases When air and blood are present the upper border of the dark area in the radiograph has a sharply defined edge while the pleural cavity above is very translucent The use of the exploring syringe generally settles the diagnosis except in certain cases in which although a considerable quantity of blood may be present none is removed by aspiration owing to the needle entering the clot

Course—This depends upon the cause and size of the hæmothorax, and upon the mode of treatment adopted It is profoundly and gravely influenced by infection of the effused blood A small sterile hæmothorax is generally absorbed spontaneously Medium sized and large effusions may not disappear unless aspirated An infected hæmothorax will inevitably prove fatal if untreated

Prognosis—In a sterile hæmothorax due to a chest wound the prognosis is good If infection occurs the prognosis depends upon the promptitude with which this condition is recognised and radically treated

Treatment—The blood in the pleural cavity and the fluid exuded from the pleura in response to the irritation of the blood form an ideal culture medium for infecting organisms All hæmothoraces should therefore be aspirated at short intervals until the pleura remains dry It is probable that the blood in the pleural space clots in most cases quite quickly that it is then defibrinated by the whipping effect of the movement of the heart and lungs then the fibrin sinks to the bottom of the pleural space on the diaphragm or is deposited on the pleura and pericardium The defibrinated fluid can be aspirated and its presence causes dilution with serous fluid until eventually the fluid becomes clear and yellow as the percentage of blood falls Incidentally the serous effusion contains fibrinogen so that the whole contents may clot again unless they are aspirated Such a clot becomes organised and forms a thick fibrous lining on the visceral and parietal pleura which impedes re expansion In such cases thoracotomy to evacuate the clot and decorticate the pleura is necessary

In view of the danger of infection it is wise to give penicillin or the sulphonamides from the start If infection takes place, treatment is the same as that for empyema (*q v*)

Hæmothorax due to rupture of adhesions or to trauma may on occasion cause severe blood loss and thoracotomy accompanied by transfusion may be necessary in order to find the bleeding point and save life Patients should be given adequate doses of iron but it is often wise to start convalescence with a transfusion of blood

CHYLOUS AND OTHER MILKY EFFUSIONS

A milky fluid is occasionally obtained on exploratory puncture or aspiration of a pleural effusion It is usual to classify such fluids into three groups—(1) Chylothorax (2) chyliform fluid (3) pseudo chylous fluid

1 CHYLOTHORAX

There is an effusion of pure chyle or of serous fluid mixed with chyle

Ætiology—Chylothorax is usually the result of injury to or disease of the thoracic duct The traumatic form is as a rule, secondary to crushing of the chest wall with fracture of the ribs In disease, the thoracic duct may be pressed on by a malignant growth or enlarged mediastinal glands or the flow may be obstructed by thrombosis of the left subclavian vein Invasion of the thoracic duct by *Filaria bancrofti* may also be a cause

Pathology—The fluid in true chylothorax is a milky emulsion which remains so on standing although a cream like layer may form at the top With the microscope fat globules can be seen, which stain with the usual fat stains and can be dissolved by ether

2 CHYLIFORM EFFUSION

In this condition fat is present but it is not derived from the thoracic duct.

Ætiology —Chyliform effusions occur in association with tuberculosis and carcinoma of the pleura or lung

Pathology —The fluid is milky and contains fat in emulsion although in smaller quantities than in true chylothorax On microscopical examination large fat droplets are seen and numbers of cells, chiefly leucocytes undergoing fatty degeneration It is no doubt, from this process that the fat is derived

3 PSEUDO CHYLOUS EFFUSION

In this condition the milky appearance is not due to fat but to other particles causing opalescence

Ætiology —Pseudo chylous fluid has beeen observed in chronic effusions due to heart disease nephritis tuberculosis and malignant disease

Pathology —The milky appearance is due in some cases to a lecithin globulin complex (Wallis and Scholberg) Other rare causes of milky opalescent or turbid effusions are the presence of particles of calcium phosphate cholesterin or filarial embryos These fluids are distinguished from the above by showing a deposit on standing

Diagnosis —This can only be established by microscopical and chemical investigation of the fluid withdrawn

Prognosis —The prognosis in most cases of milky effusions is serious owing to the gravity of the primary condition Some traumatic cases of true chylothorax recover

Treatment —The treatment is for the most part symptomatic and dependent upon the primary condition In true chylothorax removal of the fluid is inadvisable, unless it is causing dyspnœa or other symptoms of pressure The drain of fat caused by it is a serious loss especially if the tapping has to be repeated frequently In chyliform effusions there is a marked tendency to recur after removal of the fluid

PNEUMOTHORAX

In pneumothorax, gas, usually air collects between the layers of the pleura, which now becomes a real instead of a potential space When serous fluid is present as well as the gas it is called a hydro pneumothorax when pus forms the condition is described as pyo pneumothorax and when blood and gas collect the term hæmo-pneumothorax is applied

Ætiology —Pneumothorax is more common in men and the maximum incidence is between the ages of 20 and 40 years but it may occur at any age The air may gain access to the pleural cavity in the following ways (1) Through the visceral pleura from the air in the lungs and bronchi This accounts for 95 per cent or more of the cases The commonest cause is probably the rupture of a subpleural emphysematous vesicle Pulmonary tuberculosis is a much less common cause, although the ruptured vesicle may be in the scar of a healed lesion Since emphysema is an almost invariable concomitant of asthma and the severe pneumoconioses spontaneous pneumothorax is a not uncommon complication in these conditions although the diagnosis is more often made by radiological examination than by any other way Other pulmonary causes are rupture of an empyema into the lung gangrene of the lung or pulmonary abscess rupturing into the pleural space Accidental puncture of the lung during paracentesis is an extremely common event A broken rib perforating the lung can also induce it It may also occur as a complication of artificial

pneumothorax treatment especially when this is bilateral (2) Through the chest-wall as a result of penetrating wounds although pneumothorax is not a common result. An abscess in the chest wall opening externally and through the pleura or a discharging *empyema necessitatis* may be a cause (3) Through the mediastinum by ulceration of an œsophageal growth or of a diseased bronchial gland into the pleura or from accidental perforation of the œsophagus during the passage of an œsophageal bougie or œsophagoscope (4) Through the diaphragm from some hollow abdominal viscus *e g* an ulcer of the stomach or duodenum may perforate leading to the formation of a subphrenic abscess which in turn may break through the diaphragm into the pleura or through therapeutic pneumoperitoneum where there is a congenital pleuro peritoneal sinus (5) Gas may accumulate in the pleura owing to infection of a pleural effusion by gas producing organisms This is generally the result of wounds

Sudden spontaneous pneumothorax in apparently healthy persons is not very unusual and is occasionally found in the course of routine radiography It is usually known as simple benign pneumothorax The causation is not certain but it used to be regarded as tuberculous with the same significance as a pleural effusion this belief has now been discarded Brock performed thoracoscopy in some of these cases and in a proportion of them he was able to see ruptured vesicles in either generalised or localised emphysematous areas In some he found ruptured bullæ in apical scars presumably tuberculous in some a cystic appearance of the lung and in others a peculiar cuckoo spit appearance which leaked air The probability is that in the majority of cases benign spontaneous pneumothorax is due to the rupture of an emphysematous bulla however caused In most cases the lung rapidly re expands although there is a tendency to recurrence usually on the same side but occasionally on the opposite side Complete recovery is the general rule although in rare cases re expansion takes a long time and may not occur Very occasionally spontaneous hæmopneumothorax occurs The symptoms are usually more severe and a fatal result is not uncommon

The exciting cause of pneumothorax may be physical strain or violent cough but many cases occur while the patient is at rest or even during sleep

Pathology—The entrance of air between the layers of the pleura disturbs the pressure relations in the thorax in a similar way to the effusion of fluid but whereas with the latter the process is gradual in pneumothorax it is rapid and the pressure within the pleura changes from the normal negative figure to that of the atmosphere often in a few minutes or less Mediastinal and cardiac displacements like those in pleural effusion and due to the unopposed traction of the sound side are also rapidly produced The subsequent pressure relations depend upon the source of the air If the opening is in the chest wall the intrapleural pressure will remain equal to the atmospheric until the opening becomes closed If the opening is in the lung three varieties occur (1) the opening may remain patent when the pressure keeps at atmospheric level (2) the opening may be valvular permitting the entry of air into the pleura during inspiration but preventing its escape during expiration In this case the pressure in the pleura rises above that of the atmosphere and the air within it is at a positive pressure causing further cardiac and mediastinal dislocation with downward displacement of the diaphragm (3) the opening becomes sealed and there is a condition of closed pneumothorax in which the pressure may be equal to greater or less than that of the atmosphere

To demonstrate pneumothorax post mortem the necropsy may be performed under water or by a flap being made of the skin and muscles at the side of the thorax this being filled with water before puncturing the intercostal spaces A third method is to dissect carefully through an intercostal space down to the pleura, when the lung will be found to be retracted On opening the thorax the appearances vary If the air entering the pleura is sterile no inflammatory reaction occurs the pleura

remains shiny and no fluid is formed, the condition being one of simple pneumothorax If bacteria have gained access to the pleura with the ingoing air or subsequently through the opening when this remains patent either serous fluid or pus collects In the former case the condition is described as hydro pneumothorax in the latter as pyo pneumothorax The appearances of the pleural membrane are similar to those found in serofibrinous pleurisy and empyema respectively The lung is collapsed in every case of pneumothorax, and lies retracted towards the hilum and the spine In tuberculous disease, a caseous focus or small cavity just under the pleura is the most frequent cause The perforation may be a large circular rent or a small pin hole, but multiple apertures may occasionally be present The opening can usually be found, even if small by submerging the lung under water while pumping air down the trachea When extensive adhesions are present, the collapse of the lung is largely prevented and the pneumothorax is only partial In such cases the perforation is frequently near the adhesions In cases where fluid is present the diaphragm may be seen to be depressed on the affected side and its curvature lessened or reversed

Symptoms —In a considerable proportion of cases the onset is sudden and the condition of the patient becomes alarming at once On the other hand pneumothorax may develop insidiously, with surprisingly little pain and dyspnœa, so that its occurrence may be overlooked or only discovered on routine physical and radiographic examination, including a lateral film This is more likely to be the case when perforation occurs in a lung extensively diseased or when the aperture is small and the leak of air is slow In the acute form of onset the patient is seized with severe pain while coughing or engaged in some extra exertion There is often a feeling of something having given way , and at once great dyspnœa develops with signs of collapse and severe mental anguish The patient may appear blue cold and clammy breathing is rapid and shallow the temperature falls to subnormal, the heart beats quickly and the pulse becomes small and weak The patient is often restless very alarmed and unable or afraid to speak Occasionally death occurs in a few minutes As a rule, the more acute symptoms subside in a few hours but the temperature rises and the rapid breathing usually persists for some time On examination the patient will usually be found sitting up, with alæ nasi working and with rapid shallow breathing The affected side is almost or entirely immobile and is usually bulged The displacement of the cardiac impulse towards the unaffected side is generally obvious, and is almost immediate Palpation confirms the absence of movement, and vocal fremitus is found to be absent, except where the collapsed lung remains in contact with the chest wall, over which area it may be increased The exact position of the cardiac impulse should also be determined in right sided cases it will be found in the left axillary region, in left sided cases it may be under or beyond the right nipple The liver may be felt much depressed in right sided cases The note over a pneumothorax is characteristically tympanitic or drum like as a rule but in cases with positive pressure the tympany may be flat and muffled The tympanitic area should be carefully mapped out, it may be found to extend across the middle line, or to encroach on or obliterate the liver dullness in right sided cases On the other hand in partial pneumothorax, the area may be small and easily escape recognition In left sided cases the cardiac dullness may be completely wanting on that side, and a dull area found to the right of the sternum This may give a useful hint as to the diagnosis On auscultation the breath sounds are often absent but they may be present at the apex, although weak In other instances distant tubular breathing may be audible from the collapsed lung in cases with a large patent opening hollow cavernous breathing may be heard The voice sounds have an amphoric or metallic quality, and an amphoric echo may occur with any sound produced near the pneumothorax Metallic tinkling is an example of this, being the quality conveyed to râles or other adventitious sounds produced in breathing The bell sound or *bruit d airain* is a

valuable sign but is not invariably present It is elicited by listening to the chest near where a coin is placed flat on it and tapped with another Where the acoustic conditions are right for the production of these musical sounds all sounds which produce rhythmic vibrations in the pneumothorax cavity will have a ringing quality whether they are rales voice sounds breath sounds coin sounds or even heart sounds The displacement of the heart can be confirmed by auscultation and the heart sounds may be found to have a metallic character When air and fluid are present in the pleura the signs are somewhat modified There is dullness at the base which shifts its level with the patient s movements the upper limit being straight in contrast with the curved line of ordinary effusions A marked succussion splash may be heard and felt on shaking the patient or the patient may demonstrate the sign by a sudden shake or jerk

Complications and Sequelæ—Cardiac failure and rapid death occur occasionally The chief complications are due to the entry of infective organisms into the pleura leading to pleurisy and the effusion of sero fibrinous fluid or pus The sequelæ may be pleural adhesions in cases that recover especially if effusion occurs There may be also permanent collapse of the lung in long standing cases, and in pyo pneumothorax a fistula either pleuropulmonary or external may remain in spite of treatment

Diagnosis—The recognition of a large or of a complete pneumothorax is easy as a rule the signs being characteristic When a large quantity of fluid is present in an open pneumothorax the presence of air may not be recognised until after paracentesis and radiographic examination The latter gives information of the greatest value and sometimes demonstrates the presence of local pneumothorax where it has not been suspected The air space between the lung and pleura shows most clearly in radiograms and if fluid is present as well the dead level of the upper border of the shadow varying with position is most characteristic Diagnosis is more difficult in cases where pleural adhesions exist, or where the pneumothorax is small and localised Sometimes very careful positioning of the patient and very close scrutiny of the radiographic film may be necessary before the slight collapse can be seen The following conditions may give rise to difficulty and should be considered in doubtful cases (1) Total excavation of a lung or a large pulmonary cavity in either of which the note may be boxy or even tympanitic the breath sounds amphoric and the rales metallic or tinkling while the coin sound may be obtained These conditions can usually be distinguished by the flattening and retraction of the chest wall over them and the absence of cardiac displacement or if it exists the traction of the heart towards the affected side by fibrosis (2) Advanced emphysema with complete obliteration of the cardiac dullness may be confused with pneumothorax. Large bilateral bullæ may be mistaken for bilateral pneumothorax (3) Massive collapse of one lung with compensatory emphysema of the opposite side may also be mistaken for it. In both these conditions careful examination will establish the real nature (4) A subphrenic abscess containing gas (subphrenic pyo pneumothorax), in this condition the diaphragm may be displaced upwards and the note over the lower ribs may be markedly tympanitic These signs are more suggestive when right sided Succussion splash and bell sound may be elicited The heart, if displaced is pushed upwards The history of previous abdominal disease may be helpful and a radiogram may give conclusive evidence of the subphrenic origin of the condition (5) A hernia of the stomach or bowel through the diaphragm or eventration of the diaphragm all rare conditions may simulate pneumothorax but in all there is generally abdominal flattening and little if any cardiac displacement A barium meal examination will as a rule establish the nature of the condition

Course and Prognosis—The course and prognosis of pneumothorax are profoundly influenced by the cause In cases due to rupture of an emphysematous vesicle or of a small localised healed tuberculous focus where the pleura remains sterile and the aperture of entry closes the air is usually completely absorbed in a

remains shiny and no fluid is formed, the condition being one of simple pneumothorax If bacteria have gained access to the pleura with the ingoing air or subsequently through the opening when this remains patent either serous fluid or pus collects In the former case the condition is described as hydro pneumothorax, in the latter as pyo pneumothorax The appearances of the pleural membrane are similar to those found in serofibrinous pleurisy and empyema respectively The lung is collapsed in every case of pneumothorax, and lies retracted towards the hilum and the spine In tuberculous disease a caseous focus or small cavity just under the pleura is the most frequent cause The perforation may be a large circular rent or a small pin hole, but multiple apertures may occasionally be present The opening can usually be found, even if small, by submerging the lung under water while pumping air down the trachea When extensive adhesions are present, the collapse of the lung is largely prevented and the pneumothorax is only partial In such cases the perforation is frequently near the adhesions In cases where fluid is present the diaphragm may be seen to be depressed on the affected side and its curvature lessened or reversed

Symptoms —In a considerable proportion of cases the onset is sudden and the condition of the patient becomes alarming at once On the other hand pneumothorax may develop insidiously with surprisingly little pain and dyspnœa so that its occurrence may be overlooked or only discovered on routine physical and radiographic examination, including a lateral film This is more likely to be the case when perforation occurs in a lung extensively diseased or when the aperture is small and the leak of air is slow In the acute form of onset the patient is seized with severe pain while coughing or engaged in some extra exertion There is often a feeling of something having given way , and at once great dyspnœa develops with signs of collapse and severe mental anguish The patient may appear blue, cold and clammy breathing is rapid and shallow, the temperature falls to subnormal the heart beats quickly and the pulse becomes small and weak The patient is often restless very alarmed and unable or afraid to speak Occasionally death occurs in a few minutes As a rule, the more acute symptoms subside in a few hours but the temperature rises and the rapid breathing usually persists for some time On examination the patient will usually be found sitting up with alæ nasi working and with rapid shallow breathing The affected side is almost or entirely immobile and is usually bulged The displacement of the cardiac impulse towards the unaffected side is generally obvious and is almost immediate Palpation confirms the absence of movement and vocal tremitus is found to be absent, except where the collapsed lung remains in contact with the chest wall, over which area it may be increased The exact position of the cardiac impulse should also be determined in right sided cases it will be found in the left axillary region, in left sided cases it may be under or beyond the right nipple The liver may be felt much depressed in right sided cases The note over a pneumothorax is characteristically tympanitic or drum like as a rule but in cases with positive pressure the tympany may be flat and muffled The tympanitic area should be carefully mapped out, it may be found to extend across the middle line or to encroach on or obliterate the liver dullness in right sided cases On the other hand, in partial pneumothorax the area may be small and easily escape recognition In left sided cases the cardiac dullness may be completely wanting on that side, and a dull area found to the right of the sternum This may give a useful hint as to the diagnosis On auscultation the breath sounds are often absent, but they may be present at the apex, although weak In other instances distant tubular breathing may be audible from the collapsed lung in cases with a large patent opening hollow cavernous breathing may be heard The voice sounds have an amphoric or metallic quality, and an amphoric echo may occur with any sound produced near the pneumothorax Metallic tinkling is an example of this being the quality conveyed to râles or other adventitious sounds produced in breathing The bell sound or bruit d airain is a

the adjacent tissue Contrary to what might be expected extensive pleurisy is uncommon until rupture or suppuration of the cyst occurs The pressure of the cyst may lead to collapse of the contiguous areas of lung and to displacement of the heart and mediastinum

Symptoms —These may be absent until the cyst is large enough to produce pressure symptoms such as dyspnœa pain and cough There is little or no expectoration unless rupture into a bronchus occurs when cyst wall daughter cysts and hooklets may be found in it There is no fever until suppuration occurs The signs are practically identical with those of encysted pleural effusion

Complications and Sequelæ.—Rupture and suppuration are the two most important complications Rupture may take place into the lung into the pleural cavity rarely through the chest wall or through the diaphragm At the time of rupture an urticarial rash may develop This is probably an anaphylactic phenomenon associated with the liberation of toxin present in the fluid of the cyst

Diagnosis —The symptoms and signs generally suggest either pleural effusion or new growth and hydatid disease may not be suspected Obscure basic signs in patients coming from countries where hydatid disease is common should suggest special methods of investigation as to the possibility of its presence Should it be suspected aspiration is to be deprecated unless all preparations for immediate operation are complete if the diagnosis is confirmed These methods comprise radiographic examination an eosinophil count the complement fixation test, the Casoni intra dermal test and the precipitin reaction (see p 325)

Course —The cyst may be latent for some time but it usually enlarges and produces increasing symptoms culminating in rupture or suppuration Very rarely death of the cyst occurs and its contents become inspissated

Prognosis —If untreated until rupture occurs a fatal result is most probable If diagnosed and treated before rupture the prognosis is not unfavourable

Treatment.—The former practice of aspiration and injection with formalin or iodine although sometimes successful is dangerous and should be discarded Exposure of the cyst by thoracotomy and its removal entire should be the treatment if practicable or if too large it may be aspirated and then dissected out.

ACTINOMYCOSIS OF THE PLEURA

The special features of the pulmonary localisations have been described It is possible although improbable that the infection may be primarily pleural Commonly clinical manifestations point to a predominating involvement of the pleura although the primary lesions may be in adjacent structures such as the lungs mediastinum or liver

Symptoms —The symptoms and signs in such cases are those of empyema but the following points are noteworthy The empyema is rarely large and it commonly extends through the chest wall producing a local swelling which soon discharges through the skin if untreated causing a suggestive infiltration and puckering around Exploratory puncture of an actinomycotic empyema often fails since the grumous caseous material it contains may be too thick to pass through the needle

Diagnosis —The characteristic sulphur granules in the pus may draw attention to the real nature of the condition but they are not always present Direct films should always be made from the pus obtained from empyemata The streptothrix may be found in this way when culture fails If the lung is involved as well as the pleura the organism may be found in the expectoration and the nature of the pleural condition may thus be established before operation

Prognosis —Some cases respond to treatment but prognosis is in general unfavourable death resulting from exhaustion or toxæmia due to dissemination of the disease

few weeks and recovery is often complete In tuberculous cases with extensive disease, the pleura becomes infected and death usually results in a few weeks or months although with judicious treatment life may be prolonged for years in some cases especially where surgical treatment such as thoracoplasty becomes practicable In pneumothorax secondary to some grave disease such as carcinoma or gangrene the course is brief and the prognosis is grave in the extreme In cases secondary to empyema surgical treatment may be followed by complete recovery

Treatment—In the majority of cases no treatment is required other than a few day s rest, with radiological control

In rare cases of pressure pneumothorax where the distress and dyspnœa are desperate no time must be lost in putting a needle into the pleural cavity to relieve the positive pressure Any wide-bore needle will serve in an emergency but a pneumothorax induction needle attached to a tube led off to a bottle on the floor under a water seal is better As soon as possible, however the pressure should be controlled with a pneumothorax apparatus and manometer, as in some cases the dyspnœa is not relieved until a negative pressure is achieved Severe dyspnœa must not be allowed for a second longer than necessary or death may follow swiftly even after the positive pressure has been relieved Morphine should not be given to these patients until their dyspnœa has been relieved In less urgent cases where there is no suggestion of a pressure pneumothorax, gr $\frac{1}{6}$ of morphine will help to reassure a somewhat alarmed patient If the pneumothorax is a large one and there is any distress the pressure should be taken and some of the air aspirated leaving a pressure slightly below atmospheric It is best to leave small pneumothoraces untapped and in any case except in the case of valvular pneumothorax it is unwise to remove too much air since the perforation in a partially collapsed lung is more likely to heal over than in an expanded one

In cases of recurrent spontaneous pneumothorax pleurodesis by the introduction of an irritant fluid may be necessary a 10 per cent solution of silver nitrate is often used, the quantity varying from 5 to 10 minims The treatment is often painful and may be followed by excessive pleural thickening It is rarely necessary If serous fluid or pus collects in the pleura it may be withdrawn preferably by siphonage and in this case, as also with removal of air, too much should not be withdrawn in the early stages as a slight positive pressure may assist in closure of the aperture in the lung whereas a negative pressure may open it, after it has begun to close

The question of operation in pneumothorax may be difficult to decide In cases secondary to empyema resection of a part of a rib and drainage often lead to satisfactory results In cases of moderately severe or advanced tuberculosis with pyopneumothorax open operation is generally contraindicated, and if performed is liable to result in a permanently open pneumothorax It is prefereable to remove fluid from time to time by aspiration with or without air replacement until thoracoplasty can be considered Penicillin or streptomycin may be injected into the pleural cavity as for empyema Surgical methods sometimes employed are intercostal tube drainage with slight suction water sealed drainage or thoracoplasty in several stages In pneumothoraces secondary to cystic disease of the lung lobectomy may be necessary

HYDATID DISEASE OF THE PLEURA

Hydatid cysts may be primary in the pleura or may encroach on the pleura, although originating in adjacent structures such as the lung liver, spleen or mediastinum (parapleural hydatid)

Ætiology and Pathology—Primary pleural hydatid is rare but secondary invasion of the pleura is more common In this situation the cyst may reach a large size even 5 or 6 in in diameter before rupture occurs As in other situations a fibrous capsule is developed around the cyst from the irritative changes set up in

expectoration often blood stained or it may involve the chest wall Metastases sometimes develop along the course of the needle track after aspiration of the fluid The secondary growths especially those in the glands, may exert pressure, *e g* the axillary glands may cause œdema and swelling of the arm A primary growth of the pleura may cause intense pain as it may split the costal cartilage from the sternum and invade the periosteum

Diagnosis—A chronic pleural effusion in a middle aged man, not associated with fever and not due to tuberculosis should arouse suspicion of malignant disease of the lung and pleura Evidence of fluid in one pleura at an interval after excision of the breast for malignant disease is very suggestive of secondary pleural growth A hæmorrhagic effusion not due to tuberculosis or renal disease should also arouse suspicion of malignancy, especially if reaccumulation after tapping is rapid and if the subsequent tappings show increasingly hæmorrhagic characters When aspiration of a considerable quantity of fluid gives little relief to symptoms, or when irregular dull areas remain where resonance might be expected the probability of growth must be borne in mind Growth involving the chest wall or the presence of cervical or axillary glandular metastases render it certain Radiological examination after removal of some of the fluid may show characteristic plaques on the pleura

Course—This is almost invariably progressive, the duration being rarely more than 2 years and occasionally much less

Prognosis—Malignant growth of the pleura is invariably fatal unless removal is possible

Treatment—From the nature of the condition this can only be palliative Analgesic drugs may be given freely for the relief of pain morphine being reserved for the severe forms and later stages as far as possible Repeated tappings may be almost compulsory if there is much distress from the reaccumulation of the fluid but it must be remembered that in hæmorrhagic effusions the loss of blood by this means is considerable Air replacement may sometimes give relief for a longer period than simple aspiration In rare cases removal by operation may be practicable if the diagnosis is made early and the growth is localised in an accessible position Deep X ray therapy may relieve the pain

INJURY

Injury to the pleura may occur in fracture of the ribs, the fragments piercing or tearing it Similarly in penetrating wounds of the chest the pleura may be extensively lacerated It may also be torn by direct violence without breaking of the ribs and in rare cases a hernial protrusion of lung may occur forming a small swelling in an intercostal space protruding with inspiration and emptying with expiration

DISEASES OF THE DIAPHRAGM

SPASM OF THE DIAPHRAGM

Diaphragmatic spasm may be either clonic or tonic the former being termed *hiccough*

Clonic spasm—This may be due to a variety or causes namely (*a*) Alimentary

Treatment—(See p 196) The pultaceous pleural contents should be removed as far as possible by operation Penicillin should be given as for actinomycosis of the lung and injected intrapleurally

SIMPLE TUMOURS OF THE PLEURA

These are very rare and are as a rule only discovered after death They are almost invariably of extrapleural origin and their presence in the pleura is due to the direction taken by the growth Lipoma of the subpleural or of the mediastinal fat may occur as small pedunculated tumours or very rarely as a large mass They can be differentiated from tumours of the lung by radiographic examination after a diagnostic pneumothorax

MALIGNANT TUMOURS OF THE PLEURA

Primary malignant disease of the pleura is rare, and may take the form of endothelioma carcinoma or sarcoma Secondary carcinoma and sarcoma are more common

Ætiology—*Primary endothelioma of the pleura is more common* in late adult life and in the male sex Sarcoma is more likely to occur in children and in young adults Secondary growths may occur at any age but more commonly in later life

Pathology—Endothelioma of the pleura is a growth of obscure origin It has not been conclusively established that it is derived from the pleural endothelial cells and by some writers it is classed as a carcinoma It is at first unilateral but it involves the affected pleura over a wide area sometimes universally The membrane appears to be overlaid with an irregular rough hard covering sometimes nodular In other cases there is more thickening and the condition may be localised There is nearly always a large amount of blood stained serous effusion The condition may spread to the bronchial or supraclavicular glands the lung, the spine the diaphragm and the peritoneum

Primary carcinoma of the pleura has also been described but is very rare Primary sarcoma is also extremely uncommon but the round celled and spindle celled varieties may occur and angio sarcoma, fibro sarcoma myxo sarcoma and chondro sarcoma have all been recorded

Secondary carcinoma and sarcoma of the pleura are relatively *common* and may occur from direct *extension* in growths of the lung bronchi and mediastinum by *metastases* of growths in almost any distant part or by *lymphatic permeation* in mammary carcinoma *In the last named condition pleural and pulmonary growths* are a not infrequent form of recurrence sometimes occurring months or years after removal of the primary growth

Symptoms—These are not characteristic and increasing dyspnœa due to an accumulation of fluid may be the first indication More commonly pain and cough similar to those of pleurisy may occur acutely or develop more gradually Although afebrile as a rule the occurrence of fever does not exclude malignant disease Cachexia and wasting are often not marked until the condition is advanced The signs are generally indistinguishable from those of ordinary pleural effusion unless secondary growths become manifest in the cervical or axillary glands Sometimes coarse dry friction may be heard, or there may be signs of pleural thickening *without fluid* There is often local pain and tenderness over the chest Exploratory puncture may demonstrate the hæmorrhagic character of the effusion *The specific gravity* is generally 1·018 or over and *the cytology of the fluid may be suggestive* especially if excess of endothelial cells often aggregated into plaques is found

Complications—The growth may spread to the lung and cause cough and

expectoration often blood stained or it may involve the chest wall Metastases sometimes develop along the course of the needle track after aspiration of the fluid The secondary growths especially those in the glands, may exert pressure *e g* the axillary glands may cause œdema and swelling of the arm. A primary growth of the pleura may cause intense pain as it may split the costal cartilage from the sternum and invade the periosteum

Diagnosis —A chronic pleural effusion in a middle aged man, not associated with fever and not due to tuberculosis should arouse suspicion of malignant disease of the lung and pleura Evidence of fluid in one pleura at an interval after excision of the breast for malignant disease is very suggestive of secondary pleural growth A hæmorrhagic effusion not due to tuberculosis or renal disease should also arouse suspicion of malignancy, especially if reaccumulation after tapping is rapid and if the subsequent tappings show increasingly hæmorrhagic characters When aspiration of a considerable quantity of fluid gives little relief to symptoms or when irregular dull areas remain where resonance might be expected the probability of growth must be borne in mind Growth involving the chest wall or the presence of cervical or axillary glandular metastases render it certain Radiological examination after removal of some of the fluid may show characteristic plaques on the pleura

Course —This is almost invariably progressive the duration being rarely more than 2 years and occasionally much less

Prognosis —Malignant growth of the pleura is invariably fatal unless removal is possible

Treatment —From the nature of the condition this can only be palliative Analgesic drugs may be given freely for the relief of pain morphine being reserved for the severe forms and later stages as far as possible Repeated tappings may be almost compulsory if there is much distress from the reaccumulation of the fluid but it must be remembered that in hæmorrhagic effusions the loss of blood by this means is considerable Air replacement may sometimes give relief for a longer period than simple aspiration In rare cases removal by operation may be practicable if the diagnosis is made early and the growth is localised in an accessible position Deep X ray therapy may relieve the pain

INJURY

Injury to the pleura may occur in fracture of the ribs the fragments piercing or tearing it Similarly in penetrating wounds of the chest the pleura may be extensively lacerated It may also be torn by direct violence without breaking of the ribs and in rare cases a hernial protrusion of lung may occur forming a small swelling in an intercostal space protruding with inspiration and emptying with expiration

DISEASES OF THE DIAPHRAGM

SPASM OF THE DIAPHRAGM

Diaphragmatic spasm may be either clonic or tonic the former being termed *hiccough*

Clonic spasm —This may be due to a variety or causes namely (*a*) Alimentary

from irritation of the œsophagus or stomach by pungent or irritant substances such as pepper, pickles or tobacco It occurs also as a symptom in gastritis dilatation of the stomach enteritis intestinal obstruction tympanites and peritonitis, and in the late stages of debilitating disease (*b*) Nervous as in hysteria, cerebral tumour meningitis hydrocephalus epilepsy and alcoholism It may also result from peripheral nerve irritation in such conditions as mediastinal tumour mediastinitis enlarged thoracic glands, diaphragmatic pleurisy or pericardial effusion During epidemics of encephalitis lethargica hiccough has occurred as a symptom There is usually some slight pyrexia and the condition may persist without intermission for several days (*c*) Renal as in chronic nephritis and uræmia

Tonic spasm —This may be met with in tetanus strychnine poisoning laryngismus stridulus, eclampsia, epilepsy and hydrophobia If there is associated intercostal or laryngeal spasm there is grave risk of death from asphyxia

Treatment —Simple hiccough may often be relieved by holding the breath pressure on the chest or by simple inhalations such as of ammonia ether or spirits of chloroform Hiccough due to organic disease or to peripheral irritation may only be relieved by removal of the cause In epidemic hiccough, in obstinate cases of hiccough due to other causes and in the tonic form of spasm various antispasmodic measures may be tried such as trinitrin bromides or phenobarbitone by the mouth adrenaline or adrenaline and pituitary (posterior lobe) extract, hypodermically, or the inhalation of chloroform In some cases relief may be obtained by spraying the skin above the clavicle with ethyl chloride Injection of the phrenic nerve with procaine has been used with success when all other methods have failed

DIAPHRAGMATIC PLEURISY

This condition is described on p 1065 under the heading of Pleurisy

PARALYSIS OF THE DIAPHRAGM

Definition —Paralysis and inactivity of either leaf of the diaphragm or of both

Ætiology —Paralysis of the diaphragm may be caused by disease damaging the centre in the spinal cord by conditions affecting the phrenic nerve in its course or by reflex inhibition of the centre Causes involving the centre include poliomyelitis hæmorrhage into the spinal cord and tumours of the spinal cord or its membranes or of the spine itself The phrenic nerves may be affected by diphtheritic neuritis Either or both of the nerves may be compressed by mediastinal tumours or by inflammatory exudates They may be severed or injured by wounds in the neck Evulsion or crushing of the phrenic nerve is now frequently employed therapeutically, in order to promote collapse of the base of one lung and closure of cavities in cases of tuberculosis and in bronchiectasis Occasionally no cause for the paralysis may be found

Symptoms —Diaphragmatic paralysis results in the affected leaf of the diaphragm becoming immobile and remaining at a higher level in the thorax than normal or showing paradoxical movement *i e* ascending with inspiration This can easily be seen on radiographic examination Sometimes this is noted as a reversal of the ordinary abdominal movements during respiration with the result that there is epigastric recession during inspiration In elderly patients the diaphragmatic paralysis sometimes causes dyspnœa on exertion and some discomfort after meals

Treatment —This is in general, that of the condition causing the paralysis

EVENTRATION OF THE DIAPHRAGM (see p 647)

DISEASES OF THE MEDIASTINUM

The mediastinum is the interpleural space and occupies the median part of the thorax from the superior aperture above to the diaphragm below Strictly speaking any affection of any of the important structures occupying this space such as the pericardium heart great vessels air passages and the thymus might be included under this heading They are however more conveniently grouped under the various systems to which they belong and diseases of the mediastinum are commonly restricted to conditions arising in or affecting the connective tissue and glands found in this space

MEDIASTINITIS

Mediastinitis or inflammation in the mediastinal connective tissue may be acute or chronic In the acute forms there may be an inflammatory serous exudate causing œdema or the inflammation may progress to abscess formation The chronic forms are indurative or fibroid in character although chronic abscess may occur

ACUTE SIMPLE MEDIASTINITIS

Ætiology—Acute mediastinitis without suppuration may result from injuries to the chest wall or sternum, and from lacerating wounds of the œsophagus or trachea It is sometimes secondary to inflammatory processes in the lungs pleuræ, pericardium or peritoneum and to periostitis of the sternum or vertebræ Pneumonia is a not uncommon cause

Pathology—There is a hyperæmia of the mediastinal connective tissue with inflammatory œdema Mediastinal serous effusions have been described but these are without doubt encysted pleural effusions encroaching on the mediastinum

Symptoms—The clinical manifestations of acute mediastinitis are vague and not characteristic There is a mild pyrexia the temperature reaching 99 or 100° F Pain under the sternum may be complained of, and on auscultation over it a few fine crepitations *may be heard on deep breathing or they may occur synchronously with* the heart beats

Diagnosis—Mediastinitis is often not recognised or suspected since it is masked or overshadowed by the clinical manifestations of the primary condition

Course—The affection may subside or proceed to abscess formation It may result in fibroid thickening or adhesions

Treatment—No special treatment is required, apart from that appropriate to the condition inducing it

ACUTE SUPPURATIVE MEDIASTINITIS

Ætiology—Acute suppurative mediastinitis or mediastinal abscess is more common in males and may occur at any age although it is more frequently seen in early adult life than at other periods Some cases are of traumatic origin and follow perforating wounds or blows on the sternum not necessarily causing fracture Perforation or injury of the œsophagus is a comparatively frequent mode of access of pyogenic organisms to the mediastinum This may occur from ulceration of an œsophageal new growth from injury due to a swallowed body such as a tooth plate, or from the passage of an œsophagoscope or bougie Perforation of the trachea or main bronchi by an inhaled foreign body is sometimes the cause of *mediastinal suppuration* Various

pulmonary conditions may lead to pyogenic infection of the mediastinum such as pulmonary abscess or gangrene pneumonia and bronchiectasis Periostitis or osteomyelitis of the sternum, vertebræ or ribs suppuration in the mediastinal glands or tracking down of deep cervical abscesses may all lead to mediastinal abscess Extensions of pyogenic processes from the pericardium pleura or peritoneum may also be causes A suppurating hydatid or dermoid cyst may rupture into the mediastinum and lastly the infection is blood borne in some cases from infective endocarditis pyæmia erysipelas or enteric fever Dieulafoy pointed out that certain cases of empyema, originating near the mediastinum, may, by encroaching on this region induce predominating mediastinal symptoms, which he described as the 'mediastinal syndrome' Such cases although abscesses encroaching on the mediastinum are not mediastinal abscesses but are in reality special instances of encysted empyema

Pathology —The suppuration may be limited to any part of the anatomical subdivisions of the mediastinum or may spread from one compartment to another The pus sometimes tracks in various directions *e g* upwards to the neck downwards to the abdomen, or it may point in the chest wall The abscess may rupture into the œsophagus trachea aorta pleura or pericardium

Symptoms —The onset may be insidious or acute In the latter case it may be ushered in by severe pain under the sternum, radiating to the back and shoulders The symptoms may be divided into those due to the inflammatory process and those resulting from the pressure exerted by the collection of pus The former comprise malaise fever and sometimes rigors while blood examination may demonstrate a leucocytosis of 10 000 per c mm or over The pressure symptoms vary according to the amount of pus produced and its situation They include dyspnœa and paroxysmal or brassy cough from compression of the vagus nerve or direct pressure on the trachea There may also be dysphagia from obstruction of the œsophagus and hoarseness from pressure on the left recurrent laryngeal nerve Pressure on the spinal nerve roots intercostal nerves or brachial plexus may lead to severe neuralgic pains Partial or complete obstruction of the great veins may be apparent from distension of the superficial thoracic veins or of those in the neck Oedema of the chest wall is sometimes seen from this cause or it may result from the inflammatory process extending to the chest wall The signs in severe cases will be those caused by the pressure effects just described The patient looks ill distressed dyspnœic and more or less cyanosed The respirations may be noisy as there is sometimes inspiratory dyspnœa with stridor, this being known as the *bruit de cornage* The dilated veins may be apparent and the direction of the current may help to localise the seat of the obstruction There is sometimes local redness and œdema from pointing of the abscess near the sternum in the neck or in the interscapular region on either side Palpation may reveal local tenderness and even fluctuation in any of these areas There is often dullness over the sternum sometimes extending to one or other side or the dullness may be found in the interscapular region It is said that the dullness may shift with the position of the patient in some cases Breath sounds are distant and weak or bronchial over the dull area except when it is behind the sternum when they are harsh

Complications and Sequelæ —The important complications are those due to rupture of the abscess If this occurs into the lung or the œsophagus pus is expectorated, or passes into the stomach Gangrene of the mediastinum may follow, or death may occur from suffocation or hæmorrhage Extension of the abscess may lead to purulent pleurisy, pericarditis or peritonitis or to suppuration in the neck In cases that recover, chronic mediastinitis with matting together of the mediastinal contents may be a sequel

Diagnosis —The mediastinal syndrome of dyspnœa stridor paroxysmal cough hoarseness and dysphagia with signs of pressure on arteries veins and nerves is common to many conditions causing mediastinal pressure notably mediastinal

new growth enlarged mediastinal glands aneurysm and pericardial effusion The differential diagnosis of these is more fully considered under mediastinal new growth The occurrence of fevers and rigors the presence of a pointing swelling and the demonstration of a leucocytosis may give strong suggestion as to the inflammatory origin of these symptoms and signs The radiograph may reveal a localised mediastinal shadow often non pulsating although it must be remembered that in rare cases a mediastinal abscess may pulsate

Course —The disease is acute and rapidly progressive unless relieved by operation or by spontaneous external drainage in a few fortunate cases

Prognosis —This is very grave and the majority of cases die unless recognised and treated early If gangrene develops a fatal result is inevitable The outlook is more hopeful when the anterior mediastinum alone is involved

Treatment —PROPHYLACTIC —Foreign bodies in the œsophagus and trachea should be removed as soon and as gently as possible The utmost care should be exercised in the passage of a bougie or the œsophagoscope in cases of œsophageal stricture

CURATIVE —As soon as mediastinal suppuration has been diagnosed and localised surgical measures should be adopted The mediastinum can be reached by resection of pieces of costal cartilage or by trephining the sternum appropriate antibiotic treatment should be given

CHRONIC MEDIASTINITIS

This also occurs in two forms chronic indurative mediastinitis and chronic abscess

CHRONIC INDURATIVE MEDIASTINITIS —This may occur as a sequel of any form of acute mediastinitis The best known is that associated with chronic adhesive pericarditis and usually known as chronic indurative mediastino pericarditis (pp 77 883) Other forms include the chronic inflammation and thickening which occur around enlarged sclerotic and pigmented mediastinal glands and around the same glands when affected by caseous or calcareous tuberculous lesions

CHRONIC MEDIASTINAL ABSCESS is generally of tuberculous origin arising from breaking down caseous bronchial or mediastinal glands or from tuberculous disease of the spine or ribs A chronic abscess may however be caused by a foreign body such as a bullet

Symptoms —Simple indurative mediastinitis may give rise to practically no symptoms or signs Chronic abscess may cause symptoms of ill health and of mediastinal pressure or may only become apparent when it points superficially

Treatment —The treatment of chronic mediastinal abscess is practically the same as that for other cold abscesses due to tuberculosis incision and drainage being avoided if possible in favour of aspiration and chemotherapy Other cases may require operation

EMPHYSEMA OF THE MEDIASTINUM

In performing tracheotomy the pretracheal layer of deep cervical fascia is of necessity incised If difficulty arises in inserting the tube into the tracheal incision air may be drawn deep to this fascia by the vigorous attempts at respiration and thus pass into the superior mediastinum or superficial to it into the anterior mediastinum Rupture of the trachea bronchi or œsophagus or rupture of air vesicles or pulmonary lesions where the pleura is adherent may also cause it In acute interstitial emphysema of the lungs the escaped air may track along to the root and reach the mediastinum

Symptoms —Emphysema of the *mediastinum may give rise to very indefinite*

indications A few fine crackling sounds may be heard on listening over the sternum sometimes varying with respiration or with the heart movements The percussion note over the praecordium may be hyper resonant, and the heart sounds may be distant and muffled Small quantities of air escaped into the mediastinum can be rapidly absorbed and may not be of serious import

Diagnosis —This is often a matter of speculation, unless the air spreads upwards to the neck and causes superficial surgical emphysema

Prognosis —This depends entirely on that of the underlying cause, which is often of serious nature

Treatment —No special treatment is required, as a rule, apart from that of the primary condition except that pain may necessitate the use of analgesic drugs at the onset

ENLARGED MEDIASTINAL GLANDS

The mediastinal lymphatic glands are arranged in groups A few small ones are found in the anterior compartment another group is situated in the posterior mediastinum The most important of these is the tracheo bronchial group situated around the bifurcation of the trachea and extending along the bronchi It is enlargement of this group that most often gives clinical manifestations

Ætiology and Pathology —A simple inflammatory enlargement of these glands may occur in many acute affections of the bronchi and lungs and in certain acute specific fevers notably influenza pertussis and measles A more chronic enlargement associated with indurative changes results from chronic respiratory diseases such as chronic bronchitis and the pneumoconioses In the latter case, considerable pigmentary changes may be found from deposition of the particles derived from the dusty inspired air In town dwellers, these glands are often grey or black in colour from deposited carbon Tuberculosis is the commonest cause of enlargement of the mediastinal glands particularly of the tracheo bronchial group those about the right bronchus being most affected as a rule This is a frequent early localisation of tuberculous disease in children The infection spreads from the lungs in the majority of cases (Ghon) but in some instances the path of infection is from the tonsils through the cervical lymphatics and glands while in others the mode of entrance is from the intestines through the mesenteric glands The lesions may be miliary tubercles or small caseous nodules which calcify subsequently, or which may soften and lead to local spread or generalisation In other cases a fibroid hyperplasia of the gland results

Enlargement of the mediastinal glands due to sarcoidosis is now realised to be a common condition as a result of routine radiography It is often asymptomatic

In syphilis mediastinal adenitis may occur in the secondary or tertiary stages In Hodgkin s disease and in lymphatic leukæmia the mediastinal glands may share in the general adenopathy and in the former the condition may be primary in these glands Enlargement due to malignant disease is of great importance and receives separate consideration

Symptoms —These may be slight and escape notice unless the enlargement is sufficient to produce pressure or irritation Cough is the commonest symptom it is usually dry irritative noisy and ineffective It may occur in paroxysms somewhat suggestive of those of whooping cough Dyspnœa and dysphagia occur only when the enlargement is considerable Vomiting sometimes develops probably reflexly from vagal stimulation Pain behind the sternum or in the upper thoracic region posteriorly may be complained of In children with tuberculous disease in these glands there is often languor anorexia anæmia and wasting sometimes with slight irregular fever and night sweats Such symptoms in a child of 5 to 12 years of age are very suggestive The signs are also variable and frequently inconclusive

In glandular enlargement from any cause, there may be dilated veins over the front or back of the chest especially in the upper part, and a hilum dimple has been described as appearing in the second intercostal space beside the sternum on holding the breath at the end of inspiration One pupil may be larger than the other owing to sympathetic stimulation Small areas of dullness may be found at the back near the upper thoracic spines or in front close to the manubrium Breath sounds over these areas may be bronchial or harsh Occasionally the enlarged glands impede the air entry to a lower lobe generally the right in which case breath sounds are notably weakened over this area while the percussion note may be impaired Normally whispering pectoriloquy ceases at the seventh cervical spine with enlarged mediastinal glands it may be heard along the middle line or close beside it in the upper thoracic region from the first to the fifth thoracic spines This is known as d Espine s sign or tracheophony It is a confirmatory sign when other indications are present Eustace Smith s sign is of little value It consists in a venous hum audible over the manubrium sterni when the child s head is thrown back as far as possible Most of these physical signs are of historical interest only as diagnosis is unreliable without radiological information Occasionally pressure on the recurrent laryngeal nerve may lead to an abductor paralysis of one vocal cord In cases of tuberculosis syphilis Hodgkin s disease or leukæmia enlarged glands may be present in other parts of the body and may thus assist in diagnosis

Complications—A caseous gland may ulcerate into a bronchus or into the trachea and death has resulted from glottic impaction of a portion of the gland Ulceration into the œsophagus has been described Rupture into the mediastinum may lead to mediastinal abscess Invasion of the pleura lung or pericardium may occur or generalisation causing widespread miliary tuberculosis Compression by tuberculous glands may lead to lobar collapse and bronchiectasis may follow

Diagnosis—Whenever the condition of mediastinal glandular enlargement is suspected radiographic examination should be made if possible It may help to distinguish between other conditions causing mediastinal pressure such as aneurysm abscess and malignant growth Unfortunately in tuberculous disease it shows best the condition of least importance namely the old healed calcified glands The Mantoux test should be used to differentiate between tuberculosis and sarcoidosis

Prognosis—This varies with the cause being serious in Hodgkin s disease and leukæmia In tuberculous cases the prognosis is as a rule good apart from complications provided treatment is prompt and adequate The prognosis of this form of sarcoidosis is excellent

Treatment—In tuberculous adenitis the general condition should be improved by every possible means The child should be taken from school rest and exercise are to be carefully graduated and a liberal diet supplied with extra milk cream and butter Cod liver oil and malt extracts are useful In glandular enlargements due to syphilis Hodgkin s disease and leukæmia the treatment appropriate to these diseases should be employed and symptoms due to pressure relieved as far as possible Opinions differ as to whether tuberculous adenitis and the primary lesion which gives rise to it should be treated with antibiotics Undoubtedly most cases recover without but treatment with streptomycin and isoniazid should be given in very young children or where there are complications such as bronchial ulceration or compression or any suggestion of post primary spread or where the severity of symptoms suggest any doubt as to the usually favourable outcome

MEDIASTINAL TUMOURS OR NEW GROWTHS

Routine radiology and thoracic surgery have enlarged our knowledge of mediastinal tumours

NEUROGENIC TUMOURS divided into neurofibromata and ganglio neuromata are

found mainly in the posterior mediastinum Simple tumours often reach a considerable size before giving rise to any symptoms but about 15 per cent undergo malignant changes Occasionally they are associated with von Recklinghausen s neurofibromatosis

DERMOIDS and TERATOMATA are congenital cysts which are usually found in the anterior mediastinum They often give rise to no symptoms but they have a definite tendency towards malignant change

LYMPHOBLASTOMA and LYMPHOSARCOMA produce considerable mediastinal enlargement with pressure symptoms They are usually very sensitive to radiotherapy and their disappearance *after a few exposures is almost diagnostic, but they soon* recur and eventually fail to respond to radiotherapy

LYMPHADENOMA or HODGKIN S DISEASE causes mediastinal tumours similar to *those of lymphosarcoma They also respond to radiotherapy but not quite so quickly* or completely, although the effect often lasts longer

THYMOMA —This tumour is found usually in the anterior and upper part of the *chest but they may occur over the pericardium or even on a level with the diaphragm* Their presence is sometimes associated with myasthenia gravis and they sometimes become malignant

INTRATHORACIC GOITRE —Colloid goitre sometimes descends into the anterior mediastinum behind the upper end of the sternum where it may cause pressure symptoms It can sometimes be felt from above on deep inspiration or during swallowing and it often causes deviation of the trachea with respiratory symptoms

PLEURO PERICARDIAL CYSTS are simple cysts lined by flattened epithelial cells and filled with a clear colourless liquid from which they get the name Spring water cysts In origin they are congenital arising from the pleural cavity at the 15 mm embryonic stage They are found lying in the cardio phrenic angle usually on the right side, and may be circular or lobulated in outline They seldom give rise to any symptoms unless they become very large This is unusual and their chief importance clinically is due to the errors in diagnosis that may arise when they are seen in a radiograph of the chest

MEDIASTINAL GLANDS may become very massive in bronchial carcinoma so that they overshadow the primary lesion and in primary tuberculosis in children and non immune native races they may give rise to mediastinal symptoms

HYDATID CYSTS of the mediastinum are rare in this country although they arise in the more primitive agricultural countries of the Continent, the Americas and Australia

OTHER TUMOURS occasionally occur lipomata meningocele hæmangioma and chondromata are worthy of mention

Pathology —The morbid appearance depends upon the situation of origin the directions of growth and the nature of the tumour Sarcomata are generally soft pinkish in colour and vascular while carcinomata are paler and firmer There may be one large mass weighing several pounds or there may be multiple growths When the tumour reaches a considerable size it may infiltrate, surround compress or displace contiguous structures This is particularly the case in the lympho sarcomata The trachea œsophagus and large vessels may be surrounded the pericardium and heart may be extensively infiltrated and the nerve trunks may be enclosed and compressed Secondary deposits are common in other glands but not infrequently the pigmented bronchial glands may be seen entirely enclosed in growth without being infiltrated

Symptoms —The onset is often insidious and the condition may not be suspected until cachexia and pressure signs develop Malaise weakness shortness of breath cough and pain are often early symptoms which become more pronounced as the case progresses The pressure symptoms and signs constituting the mediastinal syndrome comprise—

1 *Pressure on the air passages* giving rise to dyspnœa cough and expectoration

The dyspnœa may be inspiratory and associated with stridor or expiratory and paroxysmal The cough is harsh and may be 'brassy', it is often associated with mucoid blood stained or even prune juice sputum Bronchiectasis may result in some cases

2 *Pressure on or infiltration of the lung* leading to collapse and sometimes breaking down of lung tissue If the pleura is reached or invaded pleural effusion often blood stained may result

3 *Pressure on arteries*—Compression of branches of the pulmonary artery may lead to local gangrene or in other cases the growth may ulcerate into a larger vessel and cause fatal hæmorrhage Pressure on the subclavian artery may cause inequality of the radial pulses and according to Ekgren this may only be present when the patient is lying and not when he is standing

4 *Pressure on veins*—Dilated tortuous veins may be seen over the front of the chest and abdomen or in the neck The flow of blood in these superficial veins may be reversed in direction owing to the obstruction of the superior vena cava or its main radicles The current then runs from above downwards instead of from below upwards as normally There may be œdema of the chest wall or of the face and neck from the same cause

5 *Pressure on nerves*—The vagus may be compressed causing paroxysmal dyspnœa and cough Laryngeal paralysis or spasm may result from involvement of the recurrent laryngeal nerve Dilatation of the pupil followed later by constriction drooping of the upper lid and enophthalmos occurs when the sympathetic is involved (Horner s syndrome) Paralysis of the diaphragm on one side from compression of the phrenic nerve and pain from involvement of the intercostal nerves may be present

6 *Pressure on the œsophagus* may lead to dysphagia of increasing degree

In addition to the signs afforded by these various conditions there may be glandular enlargements in the neck the suprasternal notch or in the axillæ The growth may invade the chest wall at any spot and in rare cases it may cause visible or palpable pulsation The pulmonary physical signs are dyspnœa sometimes orthopnœa and cyanosis In some instances the patient prefers to lean forward this is said to be due to the fact that in this position the antero posterior diameter of the mediastinum is increased and the tension caused by the growth is thereby lessened There may be dullness over the sternum or over the upper thoracic spines and over any part of the lung invaded or compressed by the growth The breath sounds heard over the dull area may be harsh bronchial tubular weak or absent. The signs due to any secondary condition such as bronchitis bronchiectasis or a pleural effusion may be found in addition

Complications—These include the secondary conditions just mentioned Others are due to ulceration of the growth through the chest wall or into the trachea bronchi œsophagus or aorta Pericarditis may occur if the growth invades the pericardium and hæmopericardium may result from ulceration of a vessel

Diagnosis—When signs of mediastinal pressure become apparent, new growth should be suspected in common with aneurysm mediastinal abscess or cyst enlarged mediastinal glands and pericardial effusion The history the general condition of the patient the physical signs blood examination and the radiograph may all help in distinguishing between these conditions The evidence afforded by the radiograph may be of the utmost value The pulsating shadow of an aneurysm the large area of a pericardial effusion the indefinite edge of an infiltrating growth extending into the lung may be shown clearly but the appearance should always be interpreted in the light of the other clinical features and a diagnosis should not be made on radiographic findings alone since a growth may pulsate or may give rise to an effusion while a mediastinal abscess or a cyst may give a sharp shadow An œsophageal new-growth can sometimes be differentiated by the œsophagoscope but this should only

be employed when aneurysm can be excluded Diagnosis from bronchial new growths may be almost impossible Before the onset of pressure symptoms, growth may be suspected from the cough and emaciation, and here again the radiograph may give valuable indications Chronic tuberculous disease should always be excluded by repeated sputum examinations The diagnosis of mediastinal growth may sometimes be obscured by some of the complications it induces, notably pleural effusion and bronchiectasis The rapid onset and progress of these conditions and the blood stained character of an effusion may all suggest the possibility of a malignant cause The presence of enlarged glands in the neck or axillæ or of nodular growth in the chest wall or episternal notch may afford almost conclusive evidence of malignancy

Course—Malignant growths enlarge and the course is often rapid, particularly in lympho sarcoma Fulminating cases lasting only a few weeks occur, more commonly the patients live from 6 months to 2 years from the onset rarely more Simple tumours often give rise to no symptoms and are discovered as a result of routine radiological examination

Treatment—Since simple tumours may grow in size and cause pressure symptoms or become malignant they are better removed if this is possible although if left they do not necessarily cause death or disability The treatment of inoperable malignant tumours is that of inoperable malignant disease elsewhere Deep X rays or radium treatment in some form may be tried Otherwise treatment is symptomatic and palliative Pain may be relieved by aspirin codeine or morphine Sleep may be induced if there is insomnia by chloral hydrate, papaveretum Omnopon) or other hypnotics If effusion is causing dyspnœa it may be tapped, but the fluid usually collects again rapidly

DIAPHRAGMATIC HERNIA

Definition—Protrusion of an abdominal viscus usually the stomach, through the diaphragm into the thorax

Ætiology—The condition may be congenital or acquired some of the latter being due to trauma or inflammatory necrosis The majority of cases result from a congenital defect in the development of the diaphragm Congenital herniæ are usually false, there being no covering sac as a portion of the diaphragm is missing They occur dorso laterally through the foramen of Bochdalek, posteriorly through the œsophageal hiatus or parasternally through the foramen of Morgagni The stomach omentum colon, small intestine liver duodenum pancreas cæcum or kidney may protrude into the thorax

The acquired variety when not due to trauma or necrosis constitutes the para œsophageal hernia A portion of the stomach passes through the œsophageal hiatus and being enclosed in a sac constitutes a true hernia This may be due to delay in descent of the stomach constituting a congenital short œsophagus so that the œsophageal gap around the cardiac end of the stomach is larger than that which normally occurs around the narrow lower end of the œsophagus The difference in pressure between the abdomen and thorax which is accentuated by muscular strain atrophy of the diaphragmatico œsophageal membrane which fixes the diaphragm to the lower end of the œsophagus and the cardiac end of the stomach and the fact that the œsophageal opening is lax so that it may distend when the œsophagus is filled with food are further factors which may lead to the development of a hiatus hernia Traumatic herniæ are due to wounds or crushing injuries of the thorax or abdomen which involve the diaphragm They are more common on the left side owing to the protection afforded by the liver on the right side Subphrenic abscess empyema or abdominal carcinoma may lead to inflammatory necrosis and herniation of the diaphragm The hiatus type of hernia is by far the most common clinically

Symptoms —The symptoms of congenital diaphragmatic hernia are dyspnœa cyanosis abdominal pain and distension and vomiting In many cases of hiatus hernia there are no symptoms the condition being revealed by barium meal examination In others the patient complains of dysphagia eructations hiccough abdominal pain vomiting or hæmatemesis Some of the symptoms are due to the ulceration which is sometimes found in the herniated viscus An otherwise inexplicable secondary anæmia may be due to bleeding from such a lesion

Diagnosis —The diagnosis is established by barium meal examination of the patient lying in the Trendelenberg position In some cases of hiatus hernia the symptoms may suggest disease of the gall bladder in others angina pectoris or organic lesions of the œsophagus may be simulated

Prognosis —Death often occurs in the congenital type within a few days of birth Better results are obtained by operation within 48 hours than by waiting for a week or 10 days In some series a 50 per cent cure has been obtained.

Treatment —Medical treatment consists in small and frequent feeds and avoidance of lying down shortly after a meal In the majority of cases giving rise to symptoms surgery is required various types of repair operation being performed according to the nature of the lesion

SECTION XIV

DISEASES OF THE KIDNEYS

THE CHARACTERS OF NORMAL URINE

NORMAL urine is a clear amber coloured fluid A slight gelatinous mucoid deposit, called the nubecula settles out of it on standing The quantity of urine secreted in 24 hours is about 50 oz or 1500 ml , it depends on the amount of food eaten and fluid drunk and on the amount of fluid lost by the skin lungs and bowel Solid food accounts for 33 to 50 per cent of the total fluid intake About 75 per cent. of the total intake is excreted by the kidneys but on any one day the variation may be 50 to 95 per cent of the intake The specific gravity usually varies between 1 015 and 1 025 Individual specimens may be 1 005 or less if much fluid has been drunk or 1 035 on a dry diet or as the result of much fluid being lost through the skin or bowel The concentration of chlorides and phosphates has more effect in raising the specific gravity than has urea The presence of glycosuria may make the specific gravity still higher The reaction is generally acid due to acid sodium phosphate. The total acidity is such that about 650 ml of decinormal caustic soda will neutralise the daily output but in acidosis the total acidity may be doubled even despite large doses of alkalis The *p*H of individual specimens varies between 4 7 and 10 Urine is more acid during fasting than during digestion while hydrochloric acid is being secreted in the gastric juice Protein food tends to make the urine acid, but fruit and vegetables tend to make it alkaline because the organic acids in these foods are converted into alkaline carbonates which are excreted in the urine It may be alkaline after rising in the morning due to increased activity of the respiratory centre the so called alkaline tide On decomposition either in the bladder or after evacuation the urine becomes alkaline from the conversion of urea into ammonium carbonate

The constituents of urine are partly derived from the food (exogenous) and partly from the katabolism of the tissues (endogenous) We may briefly consider the source and significance of the principal constituents

Nitrogenous constituents —The total nitrogen excreted each day on an ordinary mixed diet is about 18 grammes Of the various nitrogenous constituents urea is by far the most abundant its output being 33 g which contains 15 4 g of nitrogen or 85 per cent of the total nitrogen As so much of the urea comes directly from the food the amount of urea falls both absolutely and relatively in starvation the total nitrogen drops to 5 g or even less of which urea nitrogen forms about 60 per cent. On a diet rich in carbohydrates and fat but containing hardly any nitrogen these figures may fall still lower as the assimilation of other foodstuffs reduces the waste of tissue nitrogen to a minimum This is often forgotten and in nephritis undue importance is attached to a drop in the output of urea which is simply due to the diet prescribed being poor in nitrogen

The purine bodies are next in importance The best known is uric acid (tri oxy purine) A small quantity of the less oxidised purines xanthine and hypoxanthine is also excreted Uric acid is only excreted as such when the urine is concentrated and highly acid it normally appears as acid sodium urate (see Gout p 444)

Creatinine the anhydride of creatine is in some way related to muscle metabolism, 1 to 1 5 g are excreted daily It is unimportant in relation to kidney disease but endogenous (*i e* fasting) creatinine clearance roughly parallels inulin clearance and provides a relatively simple indication of glomerular filtration rate It is curious that the urine of the adult male contains no creatine or only traces of it whereas children

excrete both creatine and creatinine and in the female the excretion of creatine is intermittent It is however continuous in pregnancy

Ammonia is normally excreted to the extent of 0 5 to 1 g daily The kidney conserves plasma sodium by forming ammonia from protein breakdown products The increased excretion of ammonia is therefore to some extent a measure of acidosis

The pigments of urine are nitrogenous The principal one urochrome to which urine normally owes its colour though closely related to urobilin has an independent origin Even when all the bile escapes from the body through a biliary fistula the excretion of urochrome is unaltered Urobilin on the other hand is a reduction product of bile pigment The reduction is effected by bacterial action in the bowel when it is reabsorbed by the blood and excreted by the kidney Normally it is excreted as a colourless chromogen The excretion of urobilin as such may result from increased hæmolysis or from large extravasation of blood and in diseases of the liver and with intestinal putrefaction or obstruction Urobilin gives urine an orange tinge Urobilinogen changes to urobilin on exposure to light and air and this partly accounts for the higher colour of urine on standing The chief interest of uroerythrin of which normal urine contains only a trace is that it gives the urine a reddish orange colour when excreted in appreciable amount as a result of gross liver disease (new growth or cirrhosis) and congestive heart failure It is responsible for the pink colour of urates deposited from concentrated urines in these diseases Traces of two other pigments urorosein and hæmatoporphyrin are present in normal urine

Other nitrogenous constituents of the urine are hippuric acid the purine bases guanine and adenine aminoacids and peptides and traces of basic substances including trimethylguanidine putrescine and cadaverine

Non nitrogenous constituents—These are principally salts Sodium chloride is the most abundant averaging from 10 to 13 g a day It is retained whenever the body retains excess of fluid This explains the reduced output of sodium chloride in such conditions as œdema and serous exudation Reduced salt intake or loss through excessive vomiting are other causes On the other hand the output is much increased in Addison s disease A simple test for chloride is made by adding 10 drops of concentrated nitric acid to 5 ml urine and then add 5 ml 3 per cent silver nitrate solution In normal urine there is an abundant curdy precipitate of silver chloride but if the chlorides are diminished the solution merely appears milky or opalescent Urinary sulphates which are chiefly derived from the sulphur of the protein mole cule are excreted in the urine as inorganic sulphates (about 90 per cent) and the remainder as ethereal sulphates and neutral sulphur Indican (an ethereal sulphate potassium indoxyl sulphate) is present in traces in normal urine it is excreted in excessive quantity in intestinal putrefaction and in simple constipation Less importance is now attached to indicanuria than formerly but it is of interest as an example of a means namely that of conjugation by which the body renders a toxic substance innocuous The phosphates are excreted half as acid phosphates of sodium and potassium and half as earthy phosphates of calcium and magnesium The former are not precipitated on neutralisation while the latter are they come down as amorphous debris which settles as a white deposit If amorphous phosphates separate from the urine before it is passed they make it opalescent or milky (phos phaturia) The amorphous deposit of urates is distinguished from that of earthy phosphates by the fact that it occurs in acid urine is dissolved by heat (about 60 C) and is often stained pink by the adsorption of urochrome and uroerythrin

Crystalline deposits are of varied kind and are briefly as follows Crystals of ammonium magnesium phosphate (triple phosphate crystals) found in urine which has undergone ammoniacal decomposition are described as coffin lids or knife rests Crystals of calcium hydrogen phosphate are uncommon and have the form of simple needles or occur as clusters or rosettes Calcium oxalate crystals are octahedral (envelope crystals) or they may be dumbbell shaped These crystals deposited in

the urine before its passage may cause irritation of the renal pelvis with pain and hæmaturia Uric acid crystals to naked eye examination are distinctive They appear like grains of cayenne pepper at the bottom of a urine glass, and under the microscope assume varied forms like barrels prisms, needles or rods Their colour is due to adsorption of urinary pigments Other crystals to which reference may be made are the thorn apple crystals of sodium or ammonium urate the hexagon crystals of cystine, the sheaves of tyrosine and the rare yellow spherical masses of leucin Urinary deposits often contain starch granules (extraneous origin) These may be either recognised by their form or by the fact that they stain deep blue with iodine

Diastase is the only other substance of importance in the urine Ten to 30 units of diastase (the urinary diastatic index) are normally present but less will be found in some forms of impaired renal capacity and a great deal more in most pancreatic diseases A diastatic index of 50 units suggests a pancreatic lesion, while 100 or more make this certain In severe pancreatitis 300 to 500 may be found

THE ESTIMATION OF RENAL FUNCTION

Renal excretion is the most important mechanism by which the body maintains its remarkably constant chemical composition in varying conditions of nutrition and metabolism Thus renal function includes not only the concentration and elimination of metabolic waste products such as urea but also the regulation of body water and electrolytes by controlled absorption of these substances from glomerular filtrate and in some instances by tubular excretion A full assessment of renal function would involve examination of all these separate mechanisms The development of renal clearance tests has made it possible to investigate separately changes in glomerular filtration and in the tubular reabsorption and excretion of the various urinary constituents In addition abnormal excretion of a substance is often reflected in alteration of its concentration in the plasma Thus renal function may be studied by investigation of glomerular and tubular " handling ' of any blood constituent or by estimation of this substance in the body fluids

The choice and practical value of tests of renal function depends on a variety of circumstances In organic renal disease failure of tubular concentration is usually the earliest indication of impairment of function and may be detected by examination of the specific gravity of the urine or by the urea concentration test Creatinine clearance is the most practicable test for recognising early impairment of glomerular filtration The urea clearance test gives a good indication of progressive impairment of renal function but requires special precautions for accurate results and does not discriminate between organic renal insufficiency and extrarenal (circulatory) nitrogen retention The blood urea level is of obvious value in recognising more advanced failure of glomerular filtration leading to nitrogen retention but again concentration tests are necessary to exclude purely circulatory causes of reduced filtration The specific clearance tests such as inulin clearance for measuring glomerular filtration and Diodrast or *p* amino hippurate clearance for measuring renal blood flow and maximum tubular excretion are of great value in studying variations in renal function in normal subjects but their interpretation in patients with severe renal disease is often doubtful The same applies to clearance measurements of individual normal constituents of the urine Such tests are rarely indicated in the common forms of kidney disease but may be of value in the occasional cases where specific anomalies of tubular function occur in the absence of serious organic renal damage Detailed description of clearance tests is therefore not included here but some practical information on the simpler tests of renal function is given below

Urine Specific Gravity—If the patient is under observation in hospital daily examination of the first specimen of urine passed on waking provides a series of

specific gravity values which gives a useful indication of tubular concentrating power A more accurate test is performed by withholding fluids after breakfast on one day emptying the bladder last thing at night and measuring the specific gravity of the first three specimens passed at hourly intervals after waking next morning If the specific gravity does not exceed 1 020 in any specimen there is definite impairment of tubular function The presence of 1 g per 100 ml albumin in the urine raises the specific gravity 3 points A negative error may be introduced if the specific gravity is measured when the urine is still warm the values then being 3–4 points below readings taken at room temperature

The Urea Concentration Test—Fifteen grammes of urea dissolved in 100 ml water are taken in the fasting state after the bladder has been emptied The urine urea concentration at the end of 1 2 and 3 hours is then estimated (if the blood urea is considerably elevated urea need not be administered) When the urea concentration of the urine exceeds 2 g per 100 ml tubular concentrating power may be taken as unimpaired. Values below this level may however be obtained in normal subjects if absorption of urea is delayed or if the urine volume exceeds 100 ml per hour during the test

Creatinine Clearance—At low blood levels creatinine clearance is a fairly accurate measure of glomerular filtration This test requires only estimation of the creatinine concentration in the blood and in a 3 hour specimen of urine

Phenol Sulphonephthalein (*P S P*) *Excretion*—This dye is partly excreted by the renal tubules and gives a rough indication of tubular dysfunction The percentage excretion of the dye is estimated 2 hours after intramuscular injection or for more accurate information 30 minutes after intravenous injection during this period 60–70 per cent of the injected dye should be excreted in normal subjects The interpretation of results is doubtful if low urine volumes are excreted and occasionally normal figures are obtained when other tests are grossly impaired

In conclusion renal function is influenced by a wide variety of circumstances and changes in glomerular and tubular activity are so diverse that on the one hand no single test can be expected to give an accurate indication of renal impairment and on the other most tests are subject to wide normal variations and errors of interpretation From the practical point of view however the creatinine clearance test gives early evidence of impaired glomerular filtration whilst elevation of the blood urea indicates a more severe degree of glomerular impairment Whether this is due to organic renal damage or extrarenal (circulatory) factors can only be decided by other tests Tubular concentration is usually normal in conditions producing extra renal nitrogen retention an important exception being severe sodium deprivation Thus it is essential in all patients with elevation of the blood urea to look for clinical and biochemical evidence of extrarenal causes The urine specific gravity gives valuable information on tubular concentrating power but after the specific gravity becomes fixed, further deterioration in tubular function can be followed only by quantitative tests such as urine urea concentration At this stage however the blood urea level is probably a more reliable index of progress and is more easily determined

ESTIMATION OF FUNCTION OF KIDNEYS SEPARATELY

This can only be approximately determined but is a necessary preliminary to nephrectomy since it is essential that the opposite kidney shall be functioning normally Some evidence of impaired function may be obtained on intravenous pyelography when it may be seen that concentration is impaired or absent on one side Further evidence may be obtained by observing on cystoscopy the time taken for indigo carmine to appear at the ureteric orifices after intravenous injection of 5 to 10 ml of the dye If more exact information is required urine should be collected from the kidney by ureteric catheterisation The specimen can then be examined for specific gravity albumin pus and bacterial culture

ABNORMALITIES OF THE URINARY SECRETION

1 POLYURIA

Polyuria implies an increased volume in the output of urine, without reference to mere increased frequency of micturition It may be due to

1 Increase in the quantity of fluid imbibed

2 Increase in the molecular concentration of the glomerular filtrate as in diabetes mellitus Less water is thereby reabsorbed by the tubules from the glomerular filtrate

3 Elimination of sodium from the body, i e saline diuresis as after administration of salt or cortisone

4 Incapacity of diseased kidneys to excrete a concentrated urine as in chronic nephritis

5 Diabetes insipidus may arise without any discoverable cause or may be due to disease of the pituitary gland or of the overlying hypothalamus, or to damage in this neighbourhood of syphilitic meningitis of the base of the brain

2 ANURIA

This means suppression of the secretion of urine as opposed to retention and may be due to

1 Acute nephritis or nephrosis, whether the result of an infection or of drugs such as sulphonamides especially sulphathiazole and sulphapyridine turpentine, cantharides and mercuric salts

2 Bilateral obstruction to the ureters

3 Traumatic causes, such as operations on the kidney or trigone of the bladder crushing injuries of the limbs obstetric shock

4 Severe infections such as malaria Weil s disease infected abortion

5 Incompatible blood transfusion

6 Peripheral circulatory failure (shock) Here both low blood pressure and oligæmia reduce glomerular filtration

3 ALBUMINURIA

Albuminuria should be more correctly termed proteinuria—since blood serum contains two proteins—albumin and euglobulin—and either may appear in the urine though search is seldom made for the latter The ordinary tests of heat coagulation nitric acid or salicyl sulphonic acid give positive results with either The presence of euglobulin may be shown by the addition of dilute acetic acid (33 per cent) to urine in the cold The acid is added drop by drop and the precipitation of globulin is shown by an opalescence in the urine to which the acetic acid is added Mucin is also deposited by the addition of acetic acid but it is not redissolved by an excess of acid A more distinctive test is the precipitation of globulin in distilled water Single drops of urine are dropped into a glass vessel containing distilled water As the drop of urine falls through the water it assumes a ring form and the ring has a milky appearance due to precipitated globulin when the latter is present The globulin can be precipitated for quantitative examination by making the urine alkaline with ammonia and then half saturating it with ammonium sulphate

Proteinuria may be classified thus

I WITHOUT ORGANIC DISEASES OF THE KIDNEYS as in—

1 *Functional or orthostatic proteinuria* —This is common in males between puberty and adolescence it is much less common in females of the same age Dukes found it in 16 per cent of all boys entering Rugby School Protein appears in the urine

secreted in the upright posture and is absent from the urine passed on first rising but it may be present in the urine secreted during the first hour of recumbent posture There is no evidence that the amount of protein in the food influences it Severe physical exercise may excite proteinuria in healthy young adults Collier found it present in every one of the Oxford crew of 1906 after rowing a course to such a condition the term physiological proteinuria may fairly be applied When the protein appears apart from exertion the subject is often an anæmic weedy youth with a dull heavy aspect and a tendency to fainting The heart is irritable and the blood pressure unstable and fluctuates with change of posture There may also be a few hyaline casts and frequently calcium oxalate crystals In any case of proteinuria less than 0 1 per cent in amount in a boy or young man the diagnosis of a kidney lesion should not be made unless casts other than hyaline are discovered and unless the blood pressure is definitely and permanently raised If the urine passed on first rising in the morning is albumin free the albuminuria is almost certainly functional

2 *Febrile*—Any acute specific fever may be accompanied by proteinuria due to cloudy swelling of the kidney It should subside soon after the temperature falls to normal This type of albuminuria is referred to again under the heading of Toxæmic Kidney to which it more properly belongs

3 *Congestive*—In heart failure there is usually proteinuria from venous congestion of the kidneys Hyaline casts may also be found Unlike the urine of nephritis the urine is loaded with urates After an epileptic fit there is often a transitory proteinuria probably due to the congested condition of the veins during the fit For a similar reason protein is apt to be present in the urine of any unconscious person

II With Organic Diseases of the Kidneys and Urinary Tract—

1 Nephritis acute and chronic including acute suppurative nephritis focal nephritis periarteritis nodosa and pyelonephritis

2 Acute and chronic ischæmic renal disease including malignant hypertension diabetic glomerulosclerosis severe renal arteriosclerosis and renal infarction

3 Toxæmia of pregnancy and tubular nephroses

4 Amyloid disease of kidney

5 Renal tuberculosis Grawitz tumour and congenital cystic kidneys

6 All conditions of the urinary tract characterised by hæmaturia and pyuria

4 ALBUMOSURIA

Albumose or more correctly proteose may be found in urine during autolysis of the tissues It is not of clinical importance except to distinguish it from Bence Jones proteinuria Bence Jones protein which is found in considerable amounts in the urine of sufferers from multiple myeloma is not a true proteose though possessing similar solubilities It has affinities with native proteins It begins to be precipitated at 40 to 55 C but on approaching boiling point most of the precipitate is redissolved This is probably due to the influence of certain salts in the urine and is not a property of the isolated protein Since organic renal disease may complicate myelomatosis the heat test may be masked by the presence of albumin If present this should be precipitated and the heat test repeated on the filtrate Bence Jones protein also gives a ring of coagulum on contact with strong hydrochloric acid Its recognition is of great diagnostic value as it is pathognomonic of multiple myeloma (see p 1184) Sometimes the Bence Jones protein is spontaneously precipitated causing the urine to appear milky Considerable excess of phosphates may be found in this milky precipitate probably derived from the autolysis of the surrounding bone

True peptone is exceptionally found in the urine in pneumonia and phthisis but is of no clinical importance

5 HÆMATURIA

When blood is intimately mixed with the urine it is held to be in favour of its renal origin Bleeding from the bladder is more apt to occur into the last part of the urine voided while urethral bleeding is said to occur chiefly into the first part. When the quantity of renal bleeding is not great it imparts a smoky appearance to the urine, owing to the conversion of some of the hæmoglobin into methæmoglobin On spectroscopic examination methæmoglobin gives an absorption band in the red in addition to the two bands in the green characteristic of oxyhæmoglobin The chief causes of hæmaturia are best classified as follows

1 *Prerenal*—The altered condition of the blood which occurs for instance in scurvy purpura hæmorrhagica and certain hæmorrhagic fevers leads to the escape of some of the blood through the kidney without any evidence of a definite kidney lesion

2 *Lesions of the kidney* due to (*a*) Nephritis both acute and chronic Hæmaturia is a constant feature of acute nephritis and of exacerbations of chronic nephritis In acute focal nephritis (*e g* complicating subacute bacterial infection) hæmaturia may be the only sign of renal disease

(*b*) Malignant hypertension

(*c*) Local lesions of the kidney *e g* tuberculosis Grawitz tumour congenital cystic kidney, epithelioma of the renal pelvis calculus

(*d*) Renal trauma

(*e*) Infarction of the kidney

(*f*) Drugs such as sulphonamides mercury

3 *Local lesions of the urinary tract*, *e g* ureteric calculus, papilloma and carcinoma of bladder, prostatic enlargement

6 HÆMOGLOBINURIA

This is due to some hæmolytic agent It may be—

1 *Paroxysmal* as in Raynaud s disease and in syphilis Most cases are syphilitic The corpuscles are broken down by a hæmolysin which is present in the blood of 5 to 10 per cent of cases of tertiary syphilis Those who suffer from paroxysmal hæmoglobinuria are presumed to have some constitutional peculiarity which renders them susceptible to this hæmolysin The hæmolysin acts as an amboceptor unites with the red corpuscle in the cold and on return to warmth the normal complement in the plasma causes hæmolysis In addition to this there are some rare forms of non syphilitic paroxysmal hæmoglobinuria

2 *Toxic*—In this group the toxic agent produces the hæmoglobinuria without an additional factor Striking examples of this are blackwater fever (*q v*) in which the hæmoglobin is actually excreted as methæmalbumin poisoning by arseniuretted hydrogen and transfusion of incompatible blood Hæmoglobinuria may also occur in Lederer s anæmia The chemical tests for hæmoglobinuria are the same as for hæmaturia but the microscope will fail to reveal red corpuscles Some of the pigment is excreted as methæmoglobin especially after drugs of the aniline group, nitrites or potassium chlorate

7 PORPHYRINURIA and PORPHYRIA (See p 452)

8 BILIRUBINURIA

Another derivative of hæmoglobin bile pigment appears in all forms of jaundice due to obstruction of the main or intrahepatic ducts In hæmolytic jaundice such as acholuric family jaundice as the name implies bile does not appear in the urine

Bile pigment can often be recognised by noting the tingeing of the froth caused by shaking the urine but is best detected by the green colour given on addition of a solution of iodine to the urine Hunter s diazo reaction is a more delicate test for bilirubin Bile salts are often absent from the urine when bile pigment is present

9 MELANURIA

Melanin only appears in the urine in melanotic sarcoma Garrod has shown that in all other diseases in which melanuria has been recorded the test employed has been unsatisfactory The melanin is excreted as melanogen which darkens on standing and gives a black precipitate on addition of ferric chloride which is soluble in excess of the reagent yielding a black solution A more delicate test is made by the addition of sodium nitro prusside and sufficient caustic soda to render the urine alkaline The ordinary ruby red colour due to creatinine is developed The urine is now made acid with acetic acid and if melanogen is present a prussian blue colour appears

10 ALKAPTONURIA

Alkaptonuric ochronosis is an inborn error of metabolism (Garrod) It is hereditary and scarcely affects health The individual cannot complete the katabolism of the amino acids phenylalanine and tyrosine as a result 2 5 dehydroxyphenylacetic acid or homogentisic acid appears in the urine The urine reduces Benedict s solution on boiling but it does not ferment It darkens on standing or at once on the addition of alkalis It may stain the linen brown When a dilute solution of ferric chloride is allowed to fall drop by drop into urine each drop produces a transitory deep blue colour The urine reduces ammoniacal silver nitrate in the cold giving a silver mirror on the sides of the test tube The black pigment in ochronosis is noticed clinically in cartilaginous tissue An early sign of the disorder is a blue discoloration of the ears especially of the concha and antihelix and later the tragus and antitragus Triangular brown pigmentary deposits with their bases towards the cornea are noted in the scleræ Bluish discoloration of the tendons of hands also occurs In long-standing alkaptonuria a peculiar gobse gait kyphosis and a stooping posture are characteristic features These changes are due to osteoarthritis especially of the vertebral joints

(For other reducing substances in the urine including sugar see p 425)

11 KETONURIA

Ketonuria is a term used loosely to include the appearance in the urine of diacetic acid and its derivatives acetone and β oxybutyric acid Acetone however being merely a decomposition product of diacetic acid is relatively unimportant β oxybutyric acid formerly regarded as the source of diacetic acid is more saturated and less toxic and has been shown by Hurtley to be formed out of diacetic acid by the liver as an attempt at detoxication Diacetic acid is derived from the incomplete oxidation of fats or of the fatty acid groups in protein It is probably always made in small quantities but when there is an abundant consumption of carbohydrate it is completely oxidised In starvation the store of glycogen is quickly exhausted and the body chiefly lives on its fats hence ketonuria Vomiting whether persistent or cyclical will excite ketonuria though without such a degree of intoxication as to cause symptoms Any disturbance of health in infancy and childhood especially a febrile state is liable to cause ketonuria In conditions where the liver is thrown out of gear such as post anæsthetic poisoning ketonuria may occur with toxic symptoms because of the severe disturbance of all metabolic processes But there are other

agents at work besides diacetic acid which may be responsible for those symptoms Only in advanced diabetes do we find toxic symptoms directly due to diacetic acid Here there may be complete inability to utilise carbohydrates so that the body perforce lives on protein and fats If these are freely given in the food the amount of diacetic acid produced may be very large But if a diabetic be starved there is a great drop in ketonuria, showing that most of this is exogenous in origin (see Diabetes) The test used for diacetic acid is the mahogany red colour given on the addition of ferric chloride This has the disadvantage of being masked if the patient is taking salicylates The nitro prusside test was formerly regarded as showing the presence of acetone, but Piper demonstrated that it is really a much more sensitive test than ferric chloride for diacetic acid A crystal of nitro prusside of soda is dissolved in the urine and then a strong solution of ammonia is poured on the top A ring the colour of Condy s fluid speedily develops at the junction of the liquids and spreads upwards The intensity of colour is a rough measure of the degree of ketonuria The reaction is made still more sensitive by previous addition of crystals of ammonium sulphate to saturation (Rothera)

12 DRUGS WHICH ALTER THE COLOUR OF URINE

Methylene blue is used as a colouring matter of sweets and also as an ingredient of certain proprietary pills It used to be given for *Bact coli* infections of the urinary tract gonorrhœa and bilharzia or less commonly as an analgesic in rheumatism sciatica and migraine In small quantities it imparts a green colour to the urine when it may be precipitated with the mucin In larger doses it turns the urine blue It can be recognised by simple filtration because it is adsorbed on the filter papers It can be dissolved from the filter paper by chloroform, and is turned pink by the addition of alkalis Its identity is best proved by loss of colour on adding glucose and alkali Eosin may be used in sweets and turns the urine a fluorescent pink Prontosil and pyridium turn the urine a reddish orange colour though if the urine is alkaline, this may not appear until it is acidified Amidopyrine may have a like effect Rhubarb and senna may turn the urine reddish brown from the chrysophanic acid they contain The urine turns pink on the addition of an alkali Santonin turns the urine a vivid yellow, which becomes rose pink with alkalis Carbolic acid may turn the urine greenish black on standing from the formation of hydroquinone In carbolic acid poisoning the urine withdrawn by a catheter may even be found olive green without exposure to the air Other drugs which may have this effect are salol creosote naphthalene and uva ursi In chronic carboluria ochronosis may occur as in alkaptonuria

Certain drugs can readily be recognised in the urine by some colour reaction Thus salicylates are excreted as salicyluric acid which gives a violet colour on the addition of ferric chloride Copaiba which is precipitated by nitric acid can be distinguished from albumin by the solubility of the precipitate in alcohol On the addition of hydrochloric acid a urine containing copaiba turns cloudy the cloud soon becoming rose pink Iodides in urine give a blue colour with guaiacum and on the addition of hydrochloric acid impart a violet colour to chloroform shaken up with the urine

13 PYURIA

Pus may come from the urethra prostate bladder or kidney The diagnosis of the source is discussed under septic diseases of the kidney The best test for pus in the urine is the microscope If the amount of pus be considerable it will yield a ropy mass on the addition of liquor potassæ If ozonic ether is shaken with the urine bubbles of oxygen are evolved With tincture of guaiacum a blue colour may be given even without the addition of ozonic ether

14 CHYLURIA

True chyluria is due to blocking of the thoracic duct most commonly by *Filaria bancrofti* but sometimes the result of inflammatory or neoplastic conditions with consequent rupture of lymphatics of the bladder through back pressure Fat may be found in the urine in the lipæmia of diabetes, in growths of the kidney and after fracture of long bones when fat may be liberated into the circulation Accidental contamination by an oily lubricant for a catheter and fradulent addition of milk to the urine must be excluded Pseudo chyluria is due to a lecithin compound of globulin and is sometimes found when there is a great excess of globulin in the urine Unlike true fat this substance is not extracted by shaking up with ether

15 PNEUMATURIA

Osler gives the following causes for gas in the urine (1) Mechanical introduction of air in vesical irrigation or cystoscopic examination in the knee elbow position (2) Infection of the urine as by *Clostridium welchii* (3) Vesico enteric fistula An additional cause is infection with yeasts in diabetes

16 CRYSTALLINE DEPOSITS IN URINE

The chief factors in the deposit of *uric acid* crystals as such are high acidity high percentage of uric acid and poverty in mineral salts The first two are the most important especially the first Deposits of urates are usually amorphous These have already been briefly described (see p 1099) *Calcium oxalate* crystals may cause bladder irritability with increased frequency of micturition and occasionally albuminuria and hæmaturia They may arise from ingested oxalates Rhubarb spinach asparagus and sorrel are the foods most likely to produce oxaluria sufficient to excite symptoms for each contain more than 2 g of oxalic acid per kilogram though many other articles of diet contain some oxalates Some individuals seem sensitive to strawberries which however only contain 0 06 g per kilogram

17 AMINO ACIDURIA

Recent light has been thrown on the significance of amino acid excretion by paper chromatography Amino acids may appear in the urine in excess either due to an abnormally high plasma level as in liver disease or due to low renal threshold as in Fanconi s syndrome and familial cystinuria In severe liver disease such as acute yellow atrophy gross amino aciduria occurs and there may be an excess of all the common amino acids in high concentration In chronic liver disease an excess of cystine is commonly found In hereditary (familial) cystinuria cystine is continuously excreted in large quantities crystals may appear in the urine and cystine calculi tend to form in these cases lysine and arginine are also excreted in increased amount In Fanconi s syndrome the cystinuria is part of a generalised disturbance of urinary amino acid excretion and abnormal amounts of other amino acids appear in the urine Resistant rickets and deposition of cystine in the tissues (cystinosis) occur in the Fanconi syndrome but stone formation does not occur

CIRCULATORY DISTURBANCES

1 *Passive congestion* —Anything which raises the pressure in the renal vein must produce a passive congestion of the kidney Failing compensation in heart disease

and hypertension is the commonest cause, but it may also be brought about by respiratory diseases or by pressure on the renal vein by abdominal tumours or ascities A transient congestion may result from an epileptic fit

The cardiac kidney as it is called, is the most typical example of passive congestion The organ is firm and dark in colour, especially the pyramids The capsule strips normally The stellate veins are engorged The kidney may drip with blood on section and if placed in a dish after section soon exudes œdematous fluid

The urine is scanty, high coloured and of high specific gravity Unlike the urine of chronic nephritis it is loaded with urates It contains a variable amount of albumin and hyaline casts with a few red blood corpuscles if the congestion is at all considerable A moderate degree of nitrogen retention may result (up to 100 mg per cent blood urea) but tubular concentrating power is unaffected The prognosis and treatment are those of the cardiac condition causing it Stimulating diuretics are of much more service than in nephritis since there is no primary disease of the secreting structures Organic mercurial preparations are especially effective

2 *Infarction* —This may be due to embolism, *e g* in rheumatic carditis or infective endocarditis or to thrombosis in an atheromatous renal artery Obstruction of large arteries leads to anæmic infarcts, 'map like areas of coagulation necrosis roughly wedge shaped but with irregular edges and with the base reaching the surface of the organ Their formation may cause a sudden pain in the loins if they are large Either of these conditions will cause both albuminuria and hæmaturia.

3 *Thrombosis of the renal vein* —This is rare and is usually significant of a terminal infection as in a marasmic infant In thrombosis of the inferior vena cava the process may reach as high as and spread into the renal vein This would produce the same effects as the cardiac kidney but in a much more intense form Bilateral renal vein thrombosis may arise from no apparent cause and may produce a picture indistinguishable from that of nephrosis

URÆMIA

Uræmia literally means retention of urine in the blood so that by derivation the principle features should be due to failure of excretion of waste products of metabolism The functional disturbance in renal failure is however much more complex than this Excretion of waste products by the kidney is only a small part of its total function, and renal failure can only be fully understood when the kidney is considered as the chief executive organ of the homeostatic mechanism of the body That is acting under the influence of the adrenal and pituitary glands and other controlling factors not yet elucidated the kidney plays a vital part in maintaining the various body equilibria These include total water content of the body sodium and potassium regulation, acid base balance and in all probability maintenance of normal blood pressure It is obvious therefore that renal failure will produce complex and varied symptoms related to these functions The picture is further complicated by the fact that renal efficiency is itself considerably affected by disturbance of these body equilibria Thus salt deficiency alkalosis and hypotension all have a serious effect on the process of urine formation At the outset therefore it is necessary to distinguish between *extrarenal uræmia* due to these factors and *primary renal failure* due to organic disease of the kidneys and further to appreciate that the latter may be complicated by the former

NORMAL KIDNEY FUNCTION —(1) *Excretion of waste products* —These are almost entirely the end products of protein metabolism urea uric acid creatinine and ammonia In addition organic acids may be excreted either alone or after being conjugated with other substances by the liver

(2) *Acid base balance* —The cations excreted by the kidney are sodium potassium

ammonium calcium and magnesium The anions are chloride phosphate sulphate and organic acid radicals The kidney compensates for changes in the acid base balance of the blood largely by conservation of base This it performs *e g* in severe acidosis by increase in the reabsorption of sodium in the excretion of hydrogen ions and in the elaboration and excretion of ammonia by the renal tubule cells

(3) *Body water* —Excessive water drinking leads to water diuresis whilst excessive loss of fluid due to vomiting, sweating or diarrhœa leads to oliguria This com pensatory process is due to the action of the posterior pituitary anti diuretic hormone which decreases or increases reabsorption of water by the renal tubules Disorder of this mechanism is illustrated by the gross polyuria of diabetes insipidus

(4) *Electrolyte control* —Conservation of body sodium is a priority function of the kidney and the absorption of sodium by the tubules is under the direct control of the salt hormone of the adrenal cortex Breakdown of this control occurs in Addison s disease and leads to excessive sodium loss in the urine with consequent reduction in the volume of extracellular fluid The mechanism by which the renal tubules regulate potassium excretion is not fully understood Phosphate reabsorption is controlled by the parathyroid glands excessive elimination in hyperparathyroidism leads to the gross disturbance of calcium metabolism which characterises this disorder Other rare functional tubular anomalies of electrolyte control occur in nephrocalcinosis and the Fanconi syndrome

(5) *Maintenance of the arteriolar resistance* which determines diastolic blood pressure is in some way related to kidney function, since diastolic hypertension is a common feature of renal disease and experimental interference with renal blood flow in animals regularly produces high blood pressure That this is not due to renal failure in the ordinary sense of the term is shown by the fact that unilateral renal artery constriction can lead to sustained hypertension There is a possibility that the adrenal cortex is also concerned in this function of the kidney since such experi mental hypertension is abolished by adrenalectomy

Mechanism of Urine Formation —There are roughly one million nephrons in each kidney and the renal blood flow through the glomeruli is about 1 3 litres per minute *i e* one third of the cardiac output Urine is formed by a combination of glomerular filtration with selective tubular absorption Glomerular filtration is purely physical and is brought about by an effective filtration pressure which is the resultant of the blood pressure and osmotic pressure in the glomerular capillaries The glomeruli filter about 170 litres per day and the filtrate contains all the constituents of blood plasma except that protein is present in only minute amounts the specific gravity of glomerular filtrate is approximately 1 010 Clearance of substances from the blood is almost entirely a function of glomerular filtration Selective *tubular reabsorption* is responsible for changing the glomerular filtrate into urine It therefore involves the reabsorption of all the water in the glomerular filtrate except some 1 500 ml together with the greater part of the useful substances such as sugar and chloride By this massive reabsorption of water the tubules concentrate waste products particu larly urea about one hundred times Since the urine is normally hypertonic (S G 1 020 to 1 030) compared with glomerular filtrate it is obvious that the fluid absorbed by the tubules must be hypotonic *i e* in health the renal tubules do osmotic work in concentrating the urine Even when tubular function is impaired and no osmotic work is done (*i e* when the urine specific gravity is fixed at 1 010) there is still a selective reabsorption of useful substances which permits considerable concentration of urea

Primary Renal Failure —Primary renal failure is due to destruction of nephrons by organic kidney disease At the outset two main types must be recognised The more common is chronic uræmia due to progressive Bright s disease or other destruc tive lesions Less common is acute uræmia to which reference is made under the heading of Traumatic Anuria

(A) CHRONIC URÆMIA

In this form of uræmia impairment of tubular function precedes and exceeds impairment of glomerular filtration, since the epithelial cells of the tubules are more susceptible to noxious agents than is the vascular structure of the glomerulus Furthermore the kidney has a very considerable physiological reserve so that considerable organic damage may occur before the usual tests of tubular or glomerular function can be shown to be impaired We must therefore recognise three stages of renal failure

(1) *Reduction of renal reserve* —In this stage the blood urea and urinary concentrating power are both normal but tests devised to measure the total excretory mass such as diodone clearance may indicate a reduction below the normal This is found for example in severe benign essential hypertension and in renal arteriosclerosis The practical point here is that if a severe strain is imposed on the kidneys for example by a surgical operation or the onset of heart failure or hæmorrhagic shock, it may lead to a severe and sometimes fatal uræmia

(2) *The stage of impaired tubular concentrating power* —The earliest clinical symptoms of renal inefficiency appear at this stage and consist of nocturnal frequency with later polyuria and thirst The limits of specific gravity of the urine are narrowed and there is eventual fixation around 1 010 The urine urea concentration falls below 2 g per cent and this test is a useful measure of subsequent deterioration after the urine specific gravity is fixed This intermediate stage of renal impairment may persist for many years before the blood urea starts to rise Nevertheless polyuria has in most cases of chronic renal disease a limited duration owing to the progressive destruction of glomeruli Persistent polyuria is usually observed only in forms of nephritis in which the tubules are primarily or predominantly involved *e g* ascending pyelonephritis with congenital dilatation of the urinary tract

(3) *Failure of glomerular function* —In this final stage the glomerular filtrate volume falls below the limiting value at which the blood can be cleared of urea The symptoms of uræmia which follow are not however, solely attributable to elevation of blood urea, but are referable to a complex disturbance of function which has already been discussed

THE CLINICAL SYNDROME OF CHRONIC URÆMIA —The clinical syndrome of chronic uræmia results from a combination of excretory failure disturbance of body equilibria and hypertensive manifestations In general those symptoms which are due to excretory failure appear late and may be seen only in the terminal stages whilst hypertensive symptoms are often amongst the earliest manifestations of the disease Elevation of blood urea in itself is not responsible for the variety of symptoms since patients with gross nitrogen retention but without hypertension may be free from symptoms The real cause of the varied manifestations which are often attributed to the retention of waste products is quite obscure Most prominent amongst these are digestive symptoms—anorexia nausea vomiting and hiccough, diarrhœa is infrequent Anæmia is a common complication and is refractory in type Acidosis due to failure of ammonia formation by the kidney leads to the classical usually terminal harsh deep regular acidotic breathing first described by Kussmaul in diabetic acidosis Severe dehydration and sodium deficiency may be due to polyuria and vomiting and these in turn may greatly aggravate the renal failure Increased muscular irritability leading to cramps and twitchings and occasionally to tetany, are due to a complex disturbance in the ionic balance which regulates nervous and muscular excitability, no uniform abnormality of blood calcium is found Irritation of the skin is common and so called urea frost may sometimes be observed on the face There is an increased tendency to hæmorrhage which may cause purpura bleeding into joints or gastro intestinal hæmorrhage A sterile pericarditis is a not uncommon terminal complication Ultimately excretory failure results in drowsiness

disorientation and fatal coma In the very chronic uræmia which occurs in patients with little or no hypertension disturbance of calcium and phosphate excretion leads to decalcification of bone and deposition of calcium in other tissues such as the arterial walls muscles and kidneys Decalcification of the bones in young children may lead to a picture indistinguishable from vitamin D deficiency rickets while in older subjects there may be multiple cystic degeneration of bone such as occurs as a result of hyperparathyroidism marked hyperplasia of the parathyroid glands occurs in chronic uræmia

The hypertensive manifestations of chronic uræmia are referable to the heart the brain and the retina Heart failure is common in hypertensive Bright s disease and predominantly affects the left ventricle with consequent pulmonary congestion and œdema Renal asthma is the same as cardiac asthma and consists of attacks of paroxysmal usually nocturnal dyspnœa due to pulmonary œdema The development of heart failure further aggravates the renal dysfunction Organic cerebral vascular lesions occur as in any other form of hypertension If the malignant phase develops there may be attacks of encephalopathy consisting of disorientation headaches convulsions transient blindness and coma Exudates and hæmorrhages appear in the retina and when these affect the macula impairment of vision results The development of papillœdema is diagnostic of the malignant hypertensive phase Added to this picture of excretory failure and hypertension are the effects of general malnutrition and hypoproteinæmia due to anorexia vomiting and albuminuria It is not surprising therefore that in the terminal stages many patients with uræmia develop generalised œdema the mechanism of which may be partly cardiac partly renal and partly nutritional

(B) ACUTE URÆMIA

Acute uræmia is described under Traumatic Anuria (p 1128) It is characterised by a total failure of the nephron leading to suppression of urine This form of uræmia is also seen in acute nephritis when anuria occurs in the early stage

Extra Renal Nitrogen Retention —This term is preferable to extra renal uræmia since the disturbance is usually limited to a moderate elevation of blood urea (rarely over 100 mg per cent) unassociated with the various complex disorders described above The immediate cause of extrarenal nitrogen retention is some impairment of the renal circulation leading to diminished renal blood flow or lowered filtration pressure or both Such disturbances arise in oligæmic states such as result from hæmorrhage or from severe dehydration The latter may be due to repeated vomiting diarrhœa massive œdema formation or salt deficiency as in Addison s disease A similar degree of nitrogen retention is produced by severe heart failure Glomerular filtration pressure is lowered by shock or by other causes of low blood pressure such as Addison s disease In all these circulatory disturbances the effect is primarily on glomerular filtration so that the blood urea is often found to be elevated whilst tubular concentrating power is normal the urine is highly coloured and the urine output greatly diminished If the circulatory disturbance is severe and very prolonged tubular function is affected and concentrating power is diminished Epithelial cell damage may occur and a tubular nephrosis results which may resolve but leave behind calcification of the epithelium It is important to realise that primary renal failure may be aggravated by extrarenal factors and that correction of the latter may greatly improve renal function

Treatment of Uræmia —This is fully discussed under the treatment of chronic Type 1 and Type 2 nephritis (chronic uræmia) and of traumatic anuria (acute uræmia)

RENAL HYPERTENSION

The occurrence of high blood pressure in some cases of kidney disease was known to Bright The subject has in recent years gained steadily in importance as

experimental evidence has revealed the close relationship between hypertension and development of organic renal damage Goldblatt's experiment in which sustained hypertension was produced in dogs by renal artery occlusion first suggested a mechanism by which renal disease might elevate the blood pressure It has subsequently been shown that many types of experimental renal damage in different species of animals will give rise to hypertension Although it seems probable that some form of circulatory restriction is common to all, the exact nature of the hæmodynamic disturbance which leads to elevation of blood pressure is not yet understood Some important relationships have, however been established The work of Wilson and Byrom showed that sustained hypertension could be produced in rats by incomplete occlusion of one renal artery without interfering with the opposite kidney so that renal insufficiency in the usually accepted sense of the term is not necessary for the development of hypertension Furthermore, organic renal damage is not a necessary pre requisite since high levels of blood pressure were produced although the ischæmic kidney remained histologically normal It was also demonstrated in these experiments that arteriolar necroses with associated glomerular and tubular lesions found in malignant hypertension were produced in the opposite kidney but were absent from the clamped kidney From this it was deduced that the renal lesions which characterise malignant hypertension are in fact the result and not the cause of the high blood pressure in this disorder The common occurrence of similar hypertensive lesions in primary renal disease was also thereby explained Wilson and Byrom went on to postulate that since hypertension can produce occlusive renal vascular lesions a vicious circle may be established which leads to progressive renal damage and further hypertension Such a vicious circle would account for the rapidly progressive course of malignant hypertension, whether renal or essential in origin, and the dramatic manner in which progressive deterioration may be checked when the blood pressure is lowered for example by removal of a single diseased kidney indicates the possibility and importance of breaking the sequence More recent experiments have shown that renal hypertension persists after total nephrectomy so that an extra renal mechanism is in some way involved It seems probable that the adrenal cortex plays a role in this mechanism since adrenalectomy abolishes experimental renal hypertension Moreover administration of salt hormone or increase in sodium chloride intake can act as an effective substitute for the adrenal cortex in maintaining the hypertension A tentative hypothesis is put forward therefore that normally the kidneys inhibit or inactivate an extrarenal pressor mechanism which depends on electrolyte distribution in the arterioles Damage to the kidneys or their removal interferes with this renal inactivation and leads to a rise in blood pressure Much further evidence is required before this hypothesis can be regarded as established but there are many clinical observations such as the well known effect on the blood pressure of sodium restriction on the one hand or increased salt intake on the other which have an obvious relevance to this hypothesis

The varieties of high blood pressure encountered in different forms of renal disease cannot yet be fully related to the underlying lesion Chronic renal disease progressing to renal failure without hypertension is rare but may be encountered in chronic Type 2 nephritis (chronic nephrosis) amyloid disease chronic pyelonephritis and congenital lesions particularly those associated with dilatation of the urinary tract Renal hypertension becomes malignant *i e* papillœdema develops in about a third to one half of all cases *i e* much more commonly than is observed in *essential hypertension* Development of the malignant phase is usually followed by rapid deterioration of renal function and death in 6 to 12 months Nevertheless a temporary remission with subsidence of papillœdema may occasionally occur spontaneously or after reduction in the blood pressure level by sympathectomy hexamethonium drugs or salt restriction

Hypertension due to Unilateral Renal Disease.—Many cases have been

reported in which unilateral renal disease has led to the development of severe hypertension and this may be of the malignant type Secondary hypertensive changes may occur in the contralateral kidney and the histological picture of malignant nephrosclerosis is sometimes found post mortem in such kidneys It is therefore important especially in young subjects presenting with hypertension but without impairment of renal function to search for a possible unilateral lesion Intravenous pyelography may reveal a nonfunctioning kidney or unilateral hydronephrosis or gross contraction on one side with a hypertrophied kidney on the other In such cases nephrectomy may bring about prompt reversal of papillœdema and restoration of blood pressure to the normal level even after many years of severe hypertension A great variety of lesions may be found in the diseased kidney, the most common being chronic pyelonephritis in a congenitally abnormal kidney Other causes of unilateral renal disease which may lead to hypertension are atheromatous obstruction of a main renal artery tuberculosis hydronephrosis renal cysts and tumours

RENAL ŒDEMA

Anasarca was the main clinical feature described by Bright in patients with organic kidney disease Nevertheless our knowledge of the mechanism of renal œdema is no more exact than our understanding of hypertension While in the majority of patients more than one factor is involved it must be recognised that there is a form of fluid retention directly attributable to kidney disease and it is this factor which is still obscure

Pathology of Oedema —Oedema of all forms is the result of water and sodium retention in the tissues In health the extracellular fluid volume is maintained constant by a balance of physical and chemical forces The physical component is the resultant of the hydrostatic pressure of the blood and plasma protein osmotic pressure and these forces control the tissue circulation *i e* the circulation of fluid from the arterial end of the capillary into the tissues and back from the tissues into the venules Increase of hydrostatic pressure as in right heart failure or lowering of osmotic pressure due to hypoproteinæmia will favour accumulation of fluid in the tissues The chemical factors are those responsible for the maintenance of a constant extracellular fluid volume and the most important of these is the salt hormone of the adrenal cortex which directly influences reabsorption of sodium by the renal tubules Administration of the hormone in excessive doses will produce œdema as will failure of tubular function in anuria unless salt and water intake are restricted This hormonal control thus maintains a balance between intake of sodium and water tissue fluid content and excretion by the kidneys

Renal Oedema —*Characteristics* —Anasarca occurs only when both kidneys are diseased In the absence of complicating factors *e g* in acute nephritis œdema is sudden in onset and has a generalised distribution affecting the face trunk and legs It tends to be most marked in the early morning and diminishes with activity in contrast to cardiac œdema In severe cases serous effusions and pulmonary œdema may be produced Clinically the œdema can be recognised by pitting on pressure although there may be in adults retention of half a stone of excess fluid before pitting œdema is demonstrable

Causation —In many patients with Bright s disease several secondary factors play a part in the development or maintenance of œdema These are hypoproteinæmia heart failure and anæmia

Hypoproteinæmia —In the nephrotic syndrome the plasma proteins fall to a low level as a result of heavy albuminuria More albumin than globulin escapes in the urine owing to the smaller size of its molecule thus the lowering of the protein osmotic pressure of the blood is chiefly due to a fall in its albumin content It is usual to find œdema when the total proteins fall below 5 g per cent or the albumin

below 2 g per cent It is probable that hypoproteinæmia contributes to the generalised œdema of many patients with Bright s disease not only those with the nephrotic syndrome but also in the early and late stages of Type 1 nephritis when protein loss may lead to considerable lowering of plasma proteins Nevertheless even in Type 2 nephritis hypoproteinæmia is not the primary cause of œdema since in the early stages generalised œdema may be present with a normal plasma protein level and in any patient massive diuresis with disappearance of œdema may occur without any significant elevation of the blood protein level

Increased Venous Pressure —This factor may contribute to œdema in chronic hypertensive Bright s disease with manifest heart failure and in the occasional cases of acute Type 1 nephritis where heart failure is a complication It cannot however be held accountable for the generalised œdema which occurs in the majority of patients with nephritis Anæmia may contribute to œdema especially in the uræmic stage of chronic nephritis when hæmoglobin levels may fall very low The effect is probably attributable to aggravation of myocardial failure

Sodium Retention —Sodium and water retention are manifestly present in renal as in other forms of œdema restriction of salt in the diet may produce some improvement while increase in sodium intake may increase it We have at present no reason to incriminate either the adrenal cortical hormone or renal retention of sodium due to diminished glomerular filtration or increased reabsorption by the renal tubules In fact glomerular filtration tends to be high in nephrotic œdema and there is no evidence in any form of Bright s disease of inability to excrete sodium unless there is suppression of urine When renal insufficiency develops the tendency is towards excessive sodium loss due to acidosis and failure of ammonia formation by the kidney in occasional cases this may progress to gross salt deficiency There is no justification for the idea that increase in capillary permeability is a factor in salt retention since the capillaries are completely permeable to electrolytes in health and disease Increase in permeability to protein in acute nephritis has not been satisfactorily demonstrated but it is unlikely that this could play a rôle in œdema formation since the proteins themselves are in a state of dynamic equilibrium between blood and tissues

Treatment —The treatment of renal œdema is described under Acute and Chronic *Glomerulo nephritis*

BRIGHT'S DISEASE

Bright s ' Disease ' is in fact a syndrome consisting of albuminuria œdema and (usually) high blood pressure associated with organic kidney disease The majority of patients presenting with this clinical picture are suffering from glomerulo nephritis in its acute or chronic forms Other diseases which may produce the syndrome are *amyloid nephrosis chronic pyelonephritis, malignant hypertension and diabetic* glomerulosclerosis

Classification of Bright s Disease

A Nephritis
- I Glomerulo nephritis
  - Type 1 (synonym acute hæmorrhagic nephritis)
  - Type 2 (synonym parenchymatous nephritis including lipoid nephrosis)
- II Pyelonephritis

B Renal Vascular Disease
- The kidney in essential hypertension—(1) benign (2) malignant
- Senile arteriosclerosis
- Diabetic glomerulosclerosis

C Miscellaneous Conditions
- Amyloid nephrosis
- Traumatic anuria
- Toxæmia of pregnancy
- Toxic nephrosis

GLOMERULO NEPHRITIS

In describing glomerulo nephritis most of the confusion in the past has arisen because names have been given to cross sections of the disease at different stages Hence glomerulo nephritis running a continuous course in the same patient might at different times be labelled acute hæmorrhagic nephritis subacute parenchymatous nephritis chronic interstitial nephritis azotæmic nephritis This cross sectional terminology can only be avoided by a long term study of nephritis from both its clinical and pathological aspects When this approach is followed we arrive at a classification of the *courses* of nephritis such as was introduced by Volhard and Fahr in 1914 In addition recent information derived from experimental pathology and physiology of the kidney has made it possible to relate various disorders of function such as hypertension œdema and uræmia to different organic lesions of the kidney A long term clinical and pathological study of some 600 cases of Bright s disease by Ellis and his colleagues at the London Hospital showed that the many clinical syn dromes of glomerulo nephritis were related to two main types of pathological process which were termed Type 1 and Type 2 nephritis Type 1 is usually preceded by a streptococcal infection Its onset is acute with hæmaturia as a prominent feature The prognosis is good 80 to 90 per cent of patients recovering completely In the remainder according to the severity of the glomerulo nephritis death may occur in the acute stage or after a rapidly progressive course running a period of months or a slowly progressive course lasting from years to decades Type 2 nephritis has an insidious onset with œdema which tends to increase and persist for months or even years Hæmaturia is not a prominent feature but albuminuria is severe and is associated with gross depletion of plasma proteins Recovery is rare and is practically limited to cases without hypertension The great majority of patients continue with albuminuria and recurrent œdema for many years before renal failure develops The morbid anatomical changes correspond closely with these clinical courses In Type 1 nephritis the lesion is diffuse and severe at the onset but in most cases resolves completely In Type 2 nephritis there is a less intense diffuse glomerulo nephritis which gradually progresses in severity and at all stages presents a characteristic involvement of the glomerular capillaries

TYPE I NEPHRITIS

Synonyms —Acute Hæmorrhagic Nephritis Acute Diffuse Nephritis

Most cases of nephritis presenting with acute onset are of this type The disease is commonest in children and adolescents but may occur at any age

Ætiology —Scarlet fever and streptococcal tonsillitis are the common preceding infections Sometimes the patient complains of a cold or a chill without sore throat Less frequent preceding infections are otitis media pneumonia peritonitis erysipelas impetigo boils and pyogenic dermatitis Severe burns may be followed by nephritis possibly due to secondary infection In time of war nephritis may occur in epidemic form for example the trench nephritis of the War of 1914–1918 In these outbreaks the nature of the primary infection may be obscure

Pathology —Microscopically the characteristic feature in the acute stage is increase in cellularity of the glomerular tufts due to proliferation of endothelial cells and infiltration with polymorphonuclear leucocytes Hæmorrhage into Bowman s capsule

is common, and collection of red cells and leucocytes may be seen in the tubules In severe cases fibrinoid necrosis of the glomerular arterioles and even of the glomerular capillaries occurs In the rapidly progressive course the main feature is epithelial crescent formation (proliferative capsulitis) Vascular necroses are common and the tubules may show hyaline droplet degeneration, the interstitial tissue is infiltrated with acute inflammatory cells In the slowly progressive course damaged glomeruli become organised and disappear, interstitial fibrosis is extensive and in the later stages acute and chronic lesions of the glomeruli and vessels are found—focal necroses capsular adhesions necrotising arteriolitis—which are the result of severe hypertensive damage This ultimately leads to focal scarring of the kidney with marked tubular atrophy dilatation of the intervening tubules and hyaline cast formation The final stage is sometimes termed secondary contracted kidney or chronic interstitial nephritis

Symptoms —The onset is usually acute though occasionally it may be insidious In the latter instance the patient may complain of biliousness nausea vomiting and abdominal pain with headache and sometimes diarrhœa before the onset of renal symptoms In the cases with acute onset there may be more or less severe pain in the back and œdema soon develops It usually starts in the face, the legs and scrotum are generally involved next and the swelling soon spreads all over the body Occasionally the dropsy is curiously localised and fugitive Though dyspnœa is not regarded as a common feature of acute nephritis most patients admit to it on direct questioning and if cardiac failure occurs it may be a prominent symptom There is usually only slight fever though occasionally a temperature of 102° or 103 F may be reached, this may be due to persistence of the original infection The pulse rate is increased and the blood pressure is generally raised The skin may be dry and itching with occasionally a papular or erythematous eruption Retinal hæmorrhages may occur but very rarely

The urine is greatly reduced in volume and may be entirely suppressed 8 to 12 oz would be an ordinary figure It is dark in colour and usually contains obvious blood This may render the urine as dark as porter but it may be bright red or merely smoky Sometimes the blood forms a flocculent reddish brown precipitate The urine is usually loaded with albumin and casts will be found on microscopical examination At first blood casts and epithelial casts will alone be found but at a later stage granular and hyaline casts appear Leucocytes are present often in large numbers Isolated renal cells transitional epithelium and squamous cells from the lower urinary tract are also commonly found The urine is sterile on culture A sudden increase in urine output after a few days is a sign of definite improvement due to elimination of œdema fluid

Slight impairment of renal function is common the blood urea being moderately raised Some degree of impaired concentrating power is found in the more severe cases

Complications —(1) *Acute heart failure* —Shortness of breath may be a presenting feature and in severe cases acute pulmonary œdema may occur This complication is found in patients who have a marked rise in blood pressure and demands urgent treatment

(2) *Hypertensive encephalopathy* —The symptoms are sudden in onset and include convulsions blindness mental excitement severe headache, vomiting and transient palsies Coma sometimes develops Severe hypertension is present but the renal function in these patients is good With adequate treatment recovery is the rule

(3) *Infections* —Not infrequently a flare up of the primary infection or the incidence of a new infection may produce a recrudescence of the nephritis Modern therapy has lessened the risk of these infections which were previously often fatal

(4) *Oliguria* —Diminution in the urine output may be due to (1) actual suppres

sion in severe cases or (2) extrarenal factors such as vomiting gross œdema acute heart failure or therapeutic fluid restriction Marked oliguria occurs when there is severe kidney damage and most frequently when there is no hypertension

Diagnosis—The combination of dropsy hypertension albuminuria hæmaturia casts and scanty urine usually makes the diagnosis quite easy The differential diagnosis of acute nephritis from an exacerbation of chronic nephritis may be difficult Definite evidence of cardiac hypertrophy and arterial changes are in favour of the latter An infarct in the kidney which causes a pain in the back and hæmaturia may simulate nephritis but there is no œdema nor are casts present in the early stages Great reduction in the volume of urine is not usual Signs of septic endocarditis would suggest infarction In malignant nephrosclerosis there may be a smart hæmorrhage but the presence of papillœdema and the cardiovascular signs would lead to a correct diagnosis The renal hæmorrhage in the early stage of new growth of the kidney is so profuse that confusion with acute nephritis is not likely to occur Moreover epithelial casts would not be found though a large blood cast from the pelvis of the kidney is a very characteristic feature Pyelitis may give rise to some confusion as there may be small hæmorrhages especially at the beginning The presence of micro organisms in a catheter specimen and abundant pus cells in the absence of casts will generally make the diagnosis clear Moreover general dropsy does not occur in pyelitis unless it sets up severe nephritis as a sequel In any cases of hæmaturia especially when it is associated with profound constitutional disturbance loss of weight, tachycardia, continued fever and peripheral neuritis the diagnosis of periarteritis nodosa must be considered (*q v*)

Prognosis and Progressive Courses—The prognosis in Type 1 nephritis is good and 80 to 90 per cent of patients recover completely Second attacks after complete clinical recovery are extremely rare In the early stage suppression of urine is the most serious prognostic symptom and death in the acute stage is most commonly due to persistent anuria If this lasts more than a week the outlook is very grave but recovery has been known to occur after 14 days anuria In such severe cases hypertension may be absent and persistent vomiting may lead to extra renal uræmia the blood urea rising as high as 300 mg per cent Severe hypertension (around 200 mm mercury systolic) may also be a bad prognostic sign in the acute stage in terms of immediate complications *i e* left ventricular failure and hypertensive encephalopathy Heart failure as a complication has a much more serious significance than encephalopathy Persistent hæmaturia is usually evidence of a progressive lesion but recovery has occurred in cases where visible blood persisted in the urine for three months Microscopic hæmaturia has a less serious significance particularly in younger subjects since it may be orthostatic in origin and complete recovery may occur after red cells have persisted in the urine for a year or more The same is true of a persistent trace of albumin in the urine Recrudescences usually marked by return of hæmaturia during the first few weeks often following recurrence of the initial infection may greatly prolong convalescence or lead to chronic nephritis Recovery tends to be slower in the elderly than in young subjects About 5 per cent. of patients with acute nephritis die in the acute stage *i e* the first 2 or 3 weeks the causes being anuria pulmonary œdema due to heart failure or infection

(1) *Rapidly progressive course*—This occurs in about 5 per cent. of patients and is due to a severe irreversible glomerulo nephritis characterised by epithelial crescent formation Clinically there is persistent hæmaturia hypertension and œdema which is often severe and generalised Progressive renal failure occurs over a period of 6 months to 2 years and there may be a malignant hypertensive termination with papillœdema encephalopathy and left ventricular failure

(2) *Slowly progressive course*—In a series of cases of acute nephritis studied by Ellis only about 5 per cent followed this course Nevertheless in any clinic there

will be a large proportion of patients with chronic Type 1 nephritis since the disease may last for decades Moreover about half these patients will give no history of acute nephritis, but first present with symptomless albuminuria or hypertension often discovered on routine examination or with hypertensive symptoms or uræmic manifestations later in the disease The natural history and prognosis is decided by two factors the severity of the residual nephritic lesions and the incidence of hypertension. Where the nephritic damage is severe there is no hard and fast demarcation from cases running a rapidly progressive course There is severe destruction of the kidney and uræmia may develop insidiously in 5 to 10 years with or without marked hypertension Polyuria may appear when tubular concentrating power becomes impaired, but as destruction of nephrons progresses urine output returns to normal and in the final stages there is usually oliguria Anæmia is often found long before the onset of uræmia and is probably due to malnutrition In chronic renal failure refractory anæmia develops and this is in some patients the presenting feature of the disease. Further symptoms are described under uræmia (p 1010) With less severe degrees of residual renal damage the patient may continue for 30 years or more and during this stage may be free from symptoms but regular examination of the urine shows persistent albuminuria During this long stage inflammatory elements are usually absent from the urine and acute recrudescences of nephritis are rare At any time however and more commonly in males the blood pressure may be observed to rise, often over a period of months and rapid deterioration in renal function may then occur About 50 per cent of patients develop the malignant hypertension syndrome This complication may be the first manifestation of renal disease and it may be very difficult if there is no past history of acute nephritis to decide whether the hypertension is nephritic or essential In general patients with malignant essential hypertension are found to have only slight impairment of renal function when papillœdema is first discovered whereas in chronic nephritis renal failure is usually advanced at this stage Although the ultimate prognosis is poor in both conditions the results of treatment by sympathectomy or hexamethonium compounds are somewhat better in malignant essential than in malignant renal hypertension The clinical features of the malignant termination in chronic Type 1 nephritis are identical with those of malignant essential hypertension (p 914) except that symptoms of renal failure are more pronounced Attacks of hypertensive encephalopathy producing headaches blindness convulsions disorientation and coma may occur as in acute nephritis this condition is reversible and improves after the blood pressure is lowered by hexamethonium drugs In chronic nephritis however, the improvement is usually short lived because of the associated irreversible uræmia

OTHER FORMS OF ACUTE NEPHRITIS —*Acute focal nephritis* is characterised clinically by an attack of hæmaturia occurring in the course of an acute infection such as otitis media Hypertension œdema and renal failure are absent and recovery usually takes place after a few days Occasionally however attacks of focal nephritis recur at long intervals and in such patients albuminuria may persist indicating residual renal damage If the attacks continue hypertension and renal impairment eventually appear and the histological picture in this late stage is indistinguishable from that of chronic Type 1 nephritis

In subacute bacterial endocarditis nephritis when it occurs is characteristically focal but may be diffuse Histologically the focal lesion consists of glomerulitis with hæmorrhage into Bowman s capsule which leads to epithelial crescent formation and later to characteristic boat shaped collagen crescents Although this lesion was at one time thought to be embolic it is doubtful whether there is any ætiological difference between the focal and diffuse forms of glomerulo nephritis in bacterial endocarditis A similar state of affairs occurs in *Henoch Schonlein purpura* where renal involvement may take the form of hæmaturia alone or the full picture of nephritis may develop with hypertension œdema and renal failure In the latter case the prog

nosis is usually poor This form of nephritis is probably allied to that occurring in *periarteritis nodosa* which may present with a typical attack of acute nephritis and purpura In both conditions acute necrotising arteriolitis may be found in the kidney and in other organs Acute nephritis is occasionally seen in patients with acute rheumatic carditis but so rarely that the association may be fortuitous

Treatment —ACUTE STAGE —In the acute stage the patient should be put to bed and kept completely at rest as in a case of acute carditis Daily observations of the blood pressure should be made the fluid intake and urine output recorded and the urine examined for specific gravity albumin and blood Microscopic examination of the deposit for red cells leucocytes and casts should be made twice weekly Renal function te ts and plasma protein examination should be made It is important to search for any residual primary infection such as tonsillitis and to treat such infection with the appropriate dose of penicillin according to age In this way it may be hoped to avoid recrudescences which may otherwise lead to serious relapse of nephritis during the recovery period A low protein low salt high carbohydrate diet should be given to minimise protein breakdown and sodium retention In children and in co operative adults this can be very simply provided by restricting the fluid intake to 1 or 2 pints of orange juice daily with a carbohydrate diet until the acute stage of the disease has passed Diuretics and particularly potassium salts should not be given The patient must be kept in bed until pitting œdema has disappeared the blood pressure has returned to normal and the urine is free of albumin If after a period of at least 4 weeks from the onset the only residual urinary abnormalities are a faint trace of albumin and a few red cells per high power field on microscopic examination of the deposit the patient may be allowed up but periodic examination of the urine deposit for erythrocytes is advisable until these disappear in children particularly adolescents this may take up to 12 months Tonsillectomy is not advised until the nephritis has resolved and should then only be undertaken if the tonsils are obviously chronically inflamed or there is a past history of repeated sore throats

Complications —Secondary infection should be treated with an appropriate antibacterial agent penicillin being the most useful Heart failure is a definite risk when there is marked hypertension In severe cases with acute pulmonary œdema venesection is the treatment of choice If the blood pressure is very high reduction with hexamethonium salts may be worthy of trial although experience in this connection is still limited Digitalis is of questionable value and in the majority of patients spontaneous improvement occurs as the nephritis subsides The most serious complication is anuria If this persists uræmia rapidly develops and may be complicated by extrarenal nitrogen retention due to vomiting The essence of treatment is to maintain the electrolyte and fluid balance keeping a careful watch on the serum potassium as described under the treatment of traumatic anuria No attempts should be made to force diuresis by intravenous infusions and potassium salts should never be administered

Hypertensive encephalopathy occurs with about the same frequency as heart failure in patients with very high blood pressure Recent experimental work indicates that the syndrome is due to cerebral vascular spasm and in the later stages this may lead to cerebral œdema Prompt venesection with removal of 1 pint of blood will sometimes produce dramatic improvement Failing this attempts should be made to reduce the blood pressure by intramuscular injection of hexamethonium salts The cerebrospinal fluid pressure is not usually raised in the early stages but lumbar puncture should be carried out and if the pressure is high an intravenous injection of 100 ml 50 per cent sucrose solution should be given in an attempt to reduce cerebral œdema Alternatively 4 to 6 oz 25 per cent magnesium sulphate may be given per rectum but this is a less effective measure Hypertensive encephalopathy and heart failure may occur together but fortunately reduction of the blood pressure

will usually relieve both conditions There is often a slight to moderate degree of anæmia in acute nephritis probably due to the initial streptococcal infection and it should be adequately treated by iron preparations

Rapidly progressive course—In these patients the nephritis is severe and hæmaturia hypertension and œdema persist Treatment is continued as in the acute stage, and complications such as heart failure and hypertensive encephalopathy should be dealt with promptly The patient should be kept at rest in bed for at least 3 months since complete recovery may occur even after this prolonged course Diuretics must not be given nor fluids restricted if renal failure is present Tonsillectomy is to be avoided as it may aggravate the nephritis in this active stage

Slowly progressive course (chronic Type 1 nephritis)—In the long intermediate stage before the development of renal failure and severe hypertension it is most important that the patient should not be made an invalid by unnecessary or even harmful treatment There are frequently no symptoms during this time, the only findings being residual albuminuria and perhaps slight variable hypertension The old practice of protein starvation is thoroughly bad as it leads to protein deficiency iron deficiency anæmia, malnutrition and the conviction of invalidism A normal *diet should therefore be allowed so long as the renal function tests are normal* Iron should be prescribed if there is any degree of anæmia and the only necessary medical attention is a periodic examination at 3 to 6 monthly intervals when the urine and blood pressure should be tested and renal function tests occasionally carried out. In the later stages the blood pressure tends to rise progressively and renal impairment develops Headache and breathlessness may be presenting symptoms and should be treated as in benign hypertension When other analgesics fail, ergotamine tartrate sometimes relieves hypertensive headaches, especially if these are migrainous in character If left ventricular failure is severe rest in bed digitalis and mercurial diuretics are indicated The appearance of retinopathy probably justifies an attempt to reduce the blood pressure by hexamethonium derivatives When renal impairment appears, the fluid intake should under no circumstances be restricted protein in the diet should be reduced only when the blood urea rises considerably above the normal *e g to 100 mg per cent*

Anæmia should be treated by iron preparations, but when uræmia is present the anæmia is usually refractory and the only beneficial treatment is blood transfusion It is well to remember that some degree of uræmia may be due to heart failure or anæmia or even to severe hypertensive crises and some improvement may be expected if these complications are adequately treated

TYPE 2 NEPHRITIS

Synonyms—Subacute and Chronic Parenchymatous Nephritis Nephrotic Nephritis *Hydropigenous Nephritis Lipoid Nephrosis*

Type 2 nephritis is less common than Type 1 nephritis but its incidence ranks high in a clinic for renal diseases since in the majority of patients it follows a chronic course of many years duration The incidence is more uniformly distributed over the first six decades of life than that of Type 1 nephritis In young children and occasionally in adults hypertension and hæmaturia may be absent so that the condition is indistinguishable from so called lipoid nephrosis Long term clinical and histological study of such cases reveals however no clear demarcation from Type 2 nephritis and it would seem reasonable in the great majority of instances to regard lipoid nephrosis as a mild form of the latter

Ætiology—In most cases no ætiological factor is established and it is unusual to obtain a previous history of acute streptococcal infection This is no doubt partly due to the fact that albuminuria (and therefore the onset of disease) may precede the onset of œdema by months or years The development of œdema which in most cases first brings the patient to the doctor may be precipitated by severe *intercurrent*

infection or by pregnancy the common factor presumably being a lowering of the plasma protiens which upsets the balance between loss of protein in the urine and new protein formation

Pathology—The kidney is large and pale and may or may not be œdematous The kidney pattern and the demarcation of cortex from medulla are blurred, and fatty changes in the tubules and *interstitial tissue may appear as white streaks on the cut* surface The microscopic picture depends on the stage of the disease and the severity In cases with little or no hypertension the picture resembles that described in nephrosis *i e* there are minimal changes in the glomeruli consisting of bland focal necroses together with deposition of lipoid in the tubular epithelium and interstitial tissue, slight interstitial cellular infiltration may be present In more severe cases there is a diffuse proliferative glomerulitis with accentuated lobulation of the tufts and swelling of the capillary basement membrane As this lesion progresses deposits of hyaline material appear in the glomerular tufts and the glomerular capsule undergoes fibrous thickening but epithelial crescent formation is almost always absent Glomerular hyalinisation gradually and very slowly increases so that even after 10 years the characteristic glomerular lesion may still be recognisable The tubules undergo fairly diffuse atrophy and a uniform interstitial fibrosis develops but it is unusual for more than a moderate degree of renal contraction to result Vascular lesions are not conspicuous although occasional arteriolar necroses may be observed in those cases with a malignant hypertensive termination

Symptoms—It has already been stated that albuminuria discovered on routine examination may provide the first indication of the disease months or years before the appearance of œdema or other symptoms In most patients however Type 2 nephritis presents with gradual or rapid onset of œdema, which steadily increases and tends to become massive The œdema may be generalised, affecting the face hands trunk and legs It is often first noticed as puffiness of the eyelids or it may first appear as a swelling of the feet and ankles extending up the legs The patient may feel quite well apart from the disability caused by œdema On the other hand there is more usually complaint of malaise and fatigue, loss of appetite and nausea and sometimes of epigastric pain There may be cough and slight shortness of breath due to slight bronchial catarrh œdema of the lungs or hydrothorax A pericardial effusion may develop Swelling of the abdomen may be the result of œdema of the abdominal wall or ascites The face is pale and the eyelids and cheeks are puffy, but the mucous membranes are of a good colour and the blood count is usually normal The urine is reduced in quantity its specific gravity is normal it contains a large amount of albumin often amounting to 0 5 or even 1 per cent and readings of 4 per cent or even more have been recorded In mild cases the urinary deposit contains only a slight excess of cells and few or no casts while red blood corpuscles are generally absent In the more severe cases leucocytes red blood cells and granular casts are regularly found in the urine deposit The blood pressure may be normal or moderately raised There is no retinitis in the early stages Characteristic changes are found *in the blood* The plasma *albumin falls more considerably than in other* forms of Bright s disease Approximate normal figures are plasma albumin 4 g per cent globulin 2 5 g per cent, total protein 6 5 g per cent which gives an albumin globulin ratio of 1 6 to 1 In Type 2 nephritis plasma albumin may be 1 to 2 g per cent globulin 2 5 to 3 5 g per cent so that albumin globulin ratio is often less than unity The blood cholesterol may be 300 to 800 mg per cent (normal 130 to 250 mg per cent) The blood urea is often raised especially in patients with gross œdema and oliguria but concentration tests are unimpaired

Complications—These are

(1) Pulmonary œdema and cerebral œdema which occur only in cases with gross anasarca Cerebral œdema is very rare but has been observed in children after rapid generalised increase in swelling

(2) Pyogenic infection—the common ones being pneumococcal peritonitis pneumonia and erysipelas

(3) Hypertensive encephalopathy Owing to the moderate degree of blood pressure elevation this complication is not often seen but it may develop in the subacute stage when, especially in adult males, severe hypertension is sometimes encountered. The symptoms are identical with those described under Type 1 nephritis

Diagnosis—The insidious onset with œdema gross albuminuria and hypoproteinæmia is so characteristic of Type 2 nephritis that there is usually no problem of diagnosis There may be some difficulty in the early stages in distinguishing it from Type 1 nephritis running the rapidly progressive course Here also there is often gross generalised œdema and heavy albuminuria but the acute onset and greater depth of hæmaturia hypertension and renal impairment enable the separation to be made in most cases Amyloid disease of the kidney also produces generalised œdema albuminuria and hypoproteinæmia Some obvious primary infection such as bronchiectasis, osteomyelitis or tertiary syphilis is usually present the spleen may be enlarged and the Congo Red test is of particular value The nephrotic syndrome occasionally arises in the later stages of diabetic glomerulosclerosis Although Type 2 nephritis may occur in the diabetic the appearance of œdema and albuminuria in the course of chronic diabetes is usually due to this specific form of glomerular hyalinisation Disseminated lupus erythematosus may produce a glomerulo nephritis in which swelling of the capillary basement membrane resembles that seen in some cases of Type 2 nephritis and clinically the nephrotic picture may develop The associated features of disseminated lupus are however diagnostic Another rare cause of generalised œdema with gross albuminuria is bilateral renal vein thrombosis but, as a rule this diagnosis is only made post mortem It is possible that the nephrotic syndrome may arise from other causes including chemical poisons and secondary syphilis, cases of obscure origin have been described in several members of the same family

Course and Prognosis—Complete recovery is rare in Type 2 nephritis particularly in adults Clinical resolution does however, occasionally occur, sometimes after many years of persistent or recurrent œdema In children, recovery is not uncommon particularly when the features are those of nephrosis *i e* when hypertension and hæmaturia are absent In the great majority of patients however the disease runs a steadily progressive course and the prognosis is closely related to the degree of hypertension which develops With no hypertension or a moderate degree which subsides under treatment, good health often continues for many years whereas with marked elevation of blood pressure the course may be rapidly progressive Hypertension is generally more severe, and the course correspondingly shorter in men than in women Thus in men Type 2 nephritis usually continues with variable œdema moderate hypertension and considerable albuminuria after 2 or 3 years progressive renal impairment sets in and leads to uræmia 3 to 5 years from the onset of œdema often with the development of the malignant hypertension syndrome In less severe cases (more commonly women) the disease runs a slower course œdema may subside very gradually over the course of months or may recur at intervals but in the absence of hypertension the patient may lead a useful and symptom free existence for 10 or 20 years In this group the degree of albuminuria tends to diminish and the plasma proteins to rise at a variable interval after the onset Intercurrent infection may occur at any time and this is particularly serious in children with generalised œdema the common infections being pneumococcal peritonitis *pneumonia or erysipelas* Occasionally intercurrent infection is associated with an exacerbation of the nephritis and there may be frank hæmaturia during such episodes in other patients infection may precipitate a massive diuresis with subsequent reduction in the degree of albuminuria

Treatment—In the early stages particularly if examination of the urinary deposit

reveals evidence of active nephritis (i e red cells leucocytes and granular casts) treatment should follow the regime advised in acute Type 1 nephritis As a rule however the disease is in its subacute or chronic stage when the patient is first seen Even then it is advisable to insist on rest in bed so that a full assessment of the condition can be obtained Observations on the blood pressure urine renal function and plasma proteins should be made as in Type 1 nephritis and it is of value to record the patient s weight daily as this gives a useful index of changes in œdema The objectives are to rest the patient treat or prevent secondary infection counteract plasma protein depletion by a high protein diet and encourage the removal of œdema fluid Very severe generalised œdema may present an urgent problem since particularly in children fatal pulmonary œdema or cerebral œdema may result In the average case however no heroic measures are required and since the œdema is a manifestation of nephritis it cannot be expected to resolve completely until the nephritis subsides It is wise therefore to maintain complete rest and during the first week or two treatment should consist in restriction of salt intake the sodium content of the food being reduced to 0 5 g daily The diet should otherwise be adapted to please the patient Under this regime œdema will gradually diminish in most instances Rest in bed should be continued so long as red blood cells and leucocytes persist in the urine Heavy proteinuria may continue for many months after the first few weeks therefore and when œdema is no longer severe it is wise to give a high protein diet (up to 200 g daily) in an attempt to restore the depleted body protein No considerable rise in plasma proteins must be expected for 1 or 2 months or even longer If the above treatment does not succeed in reducing œdema mercurial diuretics should be given intramuscularly (Mersalyl 1 to 2 ml) twice or three times weekly at the start and once a week subsequently If the diuretic response is poor ammonium chloride may be given before the injection If salt restriction and mercurial diuretics both fail to promote diuresis acu puncture of the legs under cover of adequate doses of penicillin will always produce an effective reduction in œdema The patient should be placed in Fowler s position before this is carried out to allow the œdema fluid to gravitate to the legs When subcutaneous drainage is under way it may be found that mercurial diuretics will now produce a better response If as is frequently the case ascites and pleural effusions are present paracentesis may be necessary and again mercurial diuretics may give an improved response after this has been performed It is a common observation that massive diuresis may occur in refractory cases after an infection such as measles or pneumonia Attempts to reproduce such a response has therefore been made by T A B injections or even malaria therapy but the results are not impressive and the use of direct subcutaneous drainage under antibiotic cover has made this rather drastic therapy unnecessary

Complications —Pulmonary œdema and the much rarer complication of cerebral œdema occur only when subcutaneous swelling is gross and both should be avoidable if the measures outlined above are employed in good time Should either of these complications develop direct subcutaneous drainage should be started immediately Infections such as pneumonia pneumococcal peritonitis or erysipelas should be treated by appropriate doses of penicillin In the subacute stage of the disease hypertensive encephalopathy occasionally occurs in the rare case with severe hypertension and should be treated as in acute nephritis Iron preparations should be given if anæmia develops

Chronic Type 2 nephritis —After the initial stage continued supervision is necessary When the patient first becomes ambulant it is common for some œdema of the legs to return and this can usually be controlled by fitting full length elastic stockings which should be worn only during the day In some cases œdema continues for many months and can only be satisfactorily controlled by weekly or twice weekly injections of mercurial diuretics The *high protein low salt diet should be continued* ,

salt free bread and a substitute for table salt which does not contain sodium can now be purchased Iron should be prescribed for anæmia and any devices which may improve the patient's sense of well being, including a stimulating tonic alcohol in moderation or a seaside holiday are to be commended The main point, however, is to encourage the patient to lead a normal life and return to work, with the obvious precautions of avoiding chills and excesses of any kind It is in the nature of the disease that relapses tend to occur If these are mild, and unaccompanied by more than slight œdema, rest in bed at home is often sufficient, but if œdema increases the patient should be admitted to hospital and treated as described above In the later stages of the disease when hypertension and uræmia develop, treatment is the same as in chronic Type 1 nephritis

RENAL VASCULAR DISEASE

BENIGN ESSENTIAL HYPERTENSION

Synonym —Benign Nephrosclerosis

In this form of hypertension, renal vascular changes rarely produce clinical symptoms, the disorder being one of chronic arterial and arteriolar degeneration, and it will be necessary to make only a brief reference to it here

Pathology —The chief kidney changes are in the smaller arteries and arterioles They are described in detail on p 909 In contrast with malignant nephrosclerosis there is only hyaline and fatty degeneration of the arterioles There may be renal ischæmia and consequent irregular contraction and fibrosis of the renal parenchyma. In some cases this condition is marked and a granular contracted kidney results There is then a patchy fibrosis of glomeruli with tubular atrophy and secondary interstitial changes This fibrotic atrophy is secondary to the arterial narrowing and it is because of its patchy distribution that renal function is not impaired

Symptoms —See Benign Essential Hypertension (p 909) In some cases the urine contains a trace of albumin but this is confined to long standing cases with severe ischæmic fibrosis Given this clinical picture the differential diagnosis from chronic nephritis is made on the absence of a past history of acute nephritis and of renal failure There are occasional cases presenting with the clinical features of benign hypertension in which intravenous pyelography reveals unilateral renal disease If this is discovered in childhood or early adult life removal of the diseased kidney may be followed by recovery from the hypertension In a small proportion of cases (probably not more than 5 per cent) benign hypertension may progress to malignant hypertension and terminate in uræmia

Treatment —See that of Hypertension (p 911) the Heart in Hypertension (p 851) and Uræmia

MALIGNANT ESSENTIAL HYPERTENSION

Synonym —Malignant Nephrosclerosis

As in benign hypertension the renal changes are secondary to the vascular lesions This disease is called malignant nephrosclerosis because the kidneys are severely affected so severely in fact that fatal uræmia is the usual outcome

Pathology —The chief kidney changes are in the smaller arteries and arterioles They are described on p 913 In contrast with benign nephrosclerosis, there is in addition, fibrinous necrosis especially of the arterioles

Symptoms —These are described on p 914

Diagnosis —The differential diagnosis of malignant nephrosclerosis from chronic nephritis depends on the fact that in the former there is no past history of acute or chronic nephritis, nor is there renal œdema Further, in malignant nephrosclerosis

papillœdema usually appears whilst renal function is fairly good in fact it may be normal and there may be no albuminuria In chronic nephritis however, renal failure is usually advanced by the time papillœdema develops

Treatment—See that of Hypertension (p 911) the Heart in Hypertension (p 851) and Chronic *Uræmia (p 1122)*

NEPHROSCLEROSIS WITHOUT HYPERTENSION

Synonym—Senile or Atheromatous Kidney

In this form of kidney disease also the vascular changes are *of greater importance* than the renal and it is only necessary to deal briefly with the affection

Pathology—The kidneys show depressed red areas which are due to contraction of fibrous tissue along the distribution of particular interlobular arteries and therefore tend to be conical in form with their base to the surface of the organ There is an *absence of* cardiac hypertrophy The *glomeruli in scarred areas shrink*, and the connective tissue around them becomes condensed and thickened The degenerate glomerulus and its capsule fuse together and undergo fatty and fibrotic changes The atheromatous kidney is, therefore contracted due to atrophy following insufficient circulation with consequent fibrosis

Symptoms and Diagnosis—*There may be gradual failure of the physical and* mental powers—described by Allbutt as contraction of the spheres of bodily and mental activity —rather than the more dramatic events of malignant nephro sclerosis There is a trace or more of albumin in the urine The radial artery is thickened and tortuous The blood pressure is not high and there is an absence of cardiac hypertrophy Death by cardiac failure or intercurrent affections is the commonest ending while cerebral hæmorrhage and uræmia are unlikely

RENAL LESIONS IN DIABETES

Renal disease is now one of the commonest fatal complications of diabetes This is due to the fact that control of hyperglycæmia and ketosis by insulin has greatly *prolonged life so that the vascular complications are becoming increasingly prominent* The gradual change in the natural history of diabetes over the past 20 years has brought to light a specific form of renal involvement which is closely related to chronic vascular degeneration in other organs This condition first described by Kimmelstiel and Wilson in 1936 and named by them *intercapillary glomerulosclerosis is the commonest renal lesion in diabetes* Secondly *ischæmic* atrophy of the kidney tends to be very severe in the diabetic thirdly ascending pyelonephritis may occur in a particularly intense form leading to medullary necrosis The diabetic patient is therefore particularly liable to these three forms of renal damage In addition other types of renal disease such as glomerulo nephritis are occasionally encountered

DIABETIC GLOMERULOSCLEROSIS

Incidence—It is probable that diabetic glomerulosclerosis occurs in 10 to 20 per cent of all cases In long standing diabetes starting before the age of 15 the incidence is much higher and may reach 50 per cent Its occurrence is related to long duration of diabetes rather than to the age of the patient. Although it may be discovered within a few years of the onset of glycosuria the average duration of diabetes when the renal lesion first appears is about 10 years Thus the majority of patients first present evidence of this renal disorder in middle age The incidence is higher in females than in males Neither *severity of diabetes nor insulin* treatment play any essential role in its pathogenesis since the lesion is found in patients who have never received insulin and it is not uncommon in those who have a mild easily

controlled diabetes with little or no tendency to ketosis It would thus appear that as with the other vascular complications of the disease there is little relation between the incidence and severity of diabetic glomerulosclerosis on the one hand and the disturbance of carbohydrate metabolism on the other Apart from these factors nothing is known about the ætiology of the process

Pathology—As its name implies diabetic glomerulosclerosis consists of a degeneration of the glomerular tuft This takes the form of progressive hyalinisation but it is possible to recognise several distinct histological features The first is a nodular deposit of hyaline material in the glomerular tuft which resembles amyloid material but does not take amyloid stains this lesion is peculiar to diabetes In addition the majority of affected glomeruli show a diffuse hyaline change which is seen to be an extension into the glomerular tufts of a similar hyaline degeneration in the afferent arterioles An identical but much less conspicuous hyaline degeneration may result from senile atherosclerosis of the kidney Thirdly lipo hyaline deposits and occasional capillary aneurysms occur within the glomerular tuft and contribute to its disorganisation, focal glomerular necroses may also be found particularly if the blood pressure has been very high It will be seen therefore that diabetic glomerulosclerosis is closely associated with severe degenerative changes in the arterial system of the kidney furthermore the association is equally close with severe atheromatous change elsewhere in the body especially in the heart brain and retina Because of the severe ischæmic atrophy the kidney is usually considerably contracted and the arteries are seen to be extremely prominent

Clinical Features—Albuminuria may for a period of many years be the only manifestation of diabetic glomerulosclerosis It is variable in amount and is not usually accompanied by inflammatory elements in the urinary deposit The further development of the clinical syndrome is due not so much to the specific diabetic lesion but to other complications resulting from generalised arterial degeneration Hypertension heart failure and progressive ischæmic damage to the kidney are the most important of these Impairment of renal function is the rule although its development is very gradual In the later stages albuminuria increases to a degree which leads to a considerable reduction in the plasma protein level When this occurs and particularly when myocardial failure due to coronary disease supervenes severe generalised œdema may appear Hypertension is usually, but not invariably present and is moderate in degree malignant hypertension is only rarely encountered The final picture is one of combined heart failure and renal failure and there is often severe mental disturbance due to cerebral vascular degeneration Diabetic retinopathy will be found in practically all patients with diabetic glomerulosclerosis and diabetic peripheral neuritis usually mild in degree, is also commonly present During the later stages of the disease it is not infrequently found that the insulin requirement falls This is probably accounted for by the diminished food intake and restricted activity of the patient due to increasing incapacity

Diagnosis—When the usual investigations have excluded focal lesions such as calculus tuberculosis neoplasm cystitis and pyelitis chronic albuminuria in a diabetic patient is almost certainly due to intercapillary glomerulosclerosis with associated renal ischæmic damage The presence of retinopathy strongly supports the diagnosis as does evidence of arterial degeneration in other organs There is no specific test for the disease The association with retinopathy is so close that if renal failure is discovered in a diabetic patient in the absence of retinal changes it is highly probable that some other form of kidney disease is the cause

Prognosis—As already indicated glomerular hyalinisation and ischæmic atrophy develop very slowly and albuminuria may be present for 10 years before the late complications supervene The prognosis in fact depends rather more on the extent of vascular degeneration elsewhere in the body than on the presence of glomerulosclerosis

Treatment—Apart from control of the diabetes treatment is the same as in other patients with chronic hypertensive renal disease (see Chronic Nephritis p 1122)

ACUTE MEDULLARY NECROSIS

This is a severe suppurative pyelonephritis which leads to zonal necrosis of the renal medulla

Pathology—This is the same as in pyelonephritis except that necrosis of parenchymal tissue occurs and multiple small abscesses may be formed Severe active pyelitis is present The necrosis is obvious to the naked eye as yellowish white areas lying between the base of the renal pyramid and its papilla There may be multiple necroses in different pyramids and one or both kidneys may be involved Intercapillary glomerulosclerosis is sometimes associated with medullary necrosis

Symptoms—The symptoms may be those of acute pyelitis but more commonly the condition will be found in an elderly patient who becomes severely ill and is found in what appears to be diabetic coma The condition should indeed be suspected in any patient especially a woman who fails to recover from coma after diabetic ketosis is controlled In such circumstances the urine should be examined for pus and organisms Renal calculus or urinary obstruction may be the underlying cause of ascending infection Unless the condition responds to treatment oliguria develops and death occurs in uræmia

Treatment—Prophylaxis consists in dealing with renal calculi or any obstructive lesion of the renal tract which may be discovered in the diabetic patient The presence of pyuria in a severely ill or comatose diabetic calls for prompt and effective antibiotic therapy Sensitivity tests should be carried out on the organisms cultured from the urine and streptomycin chloramphenicol or oxytetracycline should be given according to the results General therapeutic measures are the same as for acute pyelitis

THE CONTRACTED KIDNEY

In the past various terms have been applied to the contracted kidney but the ætiology and natural history of the process have often been obscure Contraction of the kidney is due to destruction of nephrons and the development of interstitial fibrosis It will be obvious from the conditions already discussed that these changes may arise in many ways nevertheless there may be no previous history of renal disease The clinical manifestations are those of renal failure and there are often no distinguishing features to indicate the nature of the primary lesion The following are the common causes of contracted kidney

CHRONIC TYPE 1 NEPHRITIS—Some of the smallest contracted kidneys result from the slowly progressive course of Type 1 nephritis The disease may have been present for 30 or 40 years and in about half the cases there is no history of acute nephritis The renal contraction is due to a combination of the original nephritis and of subsequent hypertensive damage The former produces diffuse fibrosis and the latter focal scarring The number of surviving nephrons may be extremely small so that only occasional hypertrophied glomeruli with greatly dilated tubules are seen in each low power field

CHRONIC TYPE 2 NEPHRITIS—Renal contraction in this form of Bright s disease is usually only slight or moderate and is limited to those cases which run a slow course of 10 to 20 years Renal failure is slow in development and may be present as long as 5 years before symptoms of uræmia appear A malignant hypertensive termination is common in these cases

CHRONIC PYELONEPHRITIS—Some of the most contracted kidneys fall into this group Broad zones of interstitial scarring lead to a coarse irregularity of the kidney Contraction often affects the two kidneys unevenly and one kidney may be reduced

to a fibrous remnant whilst the other is greatly hypertrophied In such cases of unilateral renal disease severe hypertension may be present and may progress to a malignant termination The hypertrophied kidney may then show the characteristic histological changes of malignant nephrosclerosis

CONGENITAL RENAL LESIONS —Here again the kidneys may be extremely small due to a failure of development (hypoplasia) as well as to fibrotic contraction usually attributable to ascending pyelonephritis This ascending contraction ' is particularly prominent in cases of idiopathic dilatation of the renal tract An unexplained feature of congenitally small kidneys (described by Rose Bradford) is the absence of associated hypertension and cardio vascular hypertrophy Nevertheless severe hypertension occasionally occurs

MALIGNANT ESSENTIAL HYPERTENSION —As a rule the kidneys are not contracted in this disorder owing to the rapidly progressive course Occasionally, however, and particularly in older subjects the disease may progress relatively slowly over the course of 3 or 4 years There is often in these patients a preceding history of long standing benign hypertension and a moderate to severe degree of renal contraction takes place

BENIGN ESSENTIAL HYPERTENSION —Renal contraction in this disorder is unusual but is seen in moderate degree when atheroma of the renal arteries is severe The mechanism of contraction only differs from that of the senile arteriosclerotic kidney in the more extensive fatty hyaline degeneration of the arterioles, which gives a finely granular appearance to the surface due to subcapsular scarring Obstruction of one renal artery by an atheromatous plaque may reduce the affected kidney to a fibrous remnant and this is one of the unilateral lesions which may lead to hypertension In diabetes arterial degeneration is severe in the kidney, as in other organs and some contraction of the kidney is likely This will be all the greater if diabetic glomerulo sclerosis is also present

HYDRONEPHROSIS —Obstructive lesions of any kind lead to pressure atrophy of the renal parenchyma and the renal substance may be reduced to a thin layer of fibrotic tissue surrounding the hydronephrotic sac Where chronic ascending infection has been present in the early stages as in many cases of renal calculus, the kidney may be small and contracted with a minor degree of hydronephrosis

TRAUMATIC ANURIA AND ALLIED CONDITIONS

Synonyms —Acute Cortical Ischæmia, Acute Tubular Necrosis Lower Nephron Nephrosis Crush Kidney Acute Focal Interstitial Nephritis

The clinical manifestations and renal histological changes in this disorder were first adequately studied in patients who received crushing injuries to the limbs during air raids on London in the War of 1939–1945 The characteristic clinical feature is suppression of urine and little structural damage may be found in the kidney except for focal areas of tubular necrosis Since its first description the syndrome has been recognised as a sequel of a variety of widely differing ætiological factors Apart from crushing injuries it may follow prolonged application of tourniquet to a limb, any form of major surgical trauma especially gall bladder operations obstetric shock retroplacental hæmorrhage infected abortion other severe infections such as Weil s disease and blackwater fever incompatible blood transfusion sulphonamide therapy and perhaps acute poisoning with heavy metals such as mercury and bismuth

Pathology —There is a severe dysfunction of the whole nephron glomerular filtration being inhibited or grossly diminished whilst tubular reabsorption is in abeyance Histologically the only findings are occasional foci of epithelial necrosis in the distal convoluted tubules associated with slight inflammatory infiltration Blood pigment casts may be present in the tubules

Symptoms —Suppression of urine is the primary disorder and this leads to acute uræmia with vomiting, drowsiness muscular twitching and coma Purpura

may appear hypertension is slight or absent but may develop in the later stages during recovery Restoration of renal function may occur after severe oliguria lasting up to 3 weeks If the patient survives the acute stage copious polyuria develops This may however give a false impression of recovery of renal function for the urine at first approximates in composition to glomerular filtrate Since tubular reabsorption is in abeyance an output of many litres of urine may therefore correspond to only a fractional recovery of glomerular filtration and the blood urea may still continue to rise There is a danger in this stage of excessive electrolyte depletion due to failure of tubular reabsorption restoration of tubular concentrating power may not be complete for many months

Treatment—During the stages of anuria and subsequent polyuria it is essential to maintain electrolyte and fluid balance since over hydration in the anuric stage carries a grave risk of fatal pulmonary œdema Electrolyte depletion due to lack of tubular reabsorption in the polyuric stage can be equally serious Endogenous protein breakdown leads to accumulation of extracellular potassium in the absence of urinary excretion and if this is excessive death may occur from cardiac arrest Potassium salts must therefore under no circumstances be administered at this stage Protein breakdown can be reduced by high carbohydrate diet and the extracellular potassium can if necessary be reduced by intravenous insulin or sodium loaded ion exchange resin The following regime of treatment should be followed 1 litre of 40 per cent glucose is given daily by intra gastric drip If any urine is passed an equal volume of extra water is added If vomiting occurs saline solution equivalent to that lost in the vomit is added If vomiting persists oral treatment is discontinued and 1 litre of 40 per cent. glucose is given intravenously by catheter via the saphenous vein into the inferior vena cava Half a million units of penicillin should be given daily intra muscularly A rise of serum potassium above 6 m Eq/litre may be dealt with in the first instance by the injection of insulin two to three times daily when the blood sugar is above normal If the rise in serum potassium continues sodium sulphonic ion exchange resin should be given orally (15 g t d s) or if this cannot be tolerated 30 g daily per rectum This form of conservative treatment has replaced the use of the artificial kidney In the stage of polyuria sodium depletion may occur so that the fluid and electrolyte intake must be increased to compensate for the amount lost in the urine

TOXIC NEPHROSIS AND RELATED DEGENERATIVE RENAL LESIONS

The term nephrosis means tubular epithelial degeneration consequently many unrelated conditions are included under this heading The types of tubular degeneration are albuminous lipoid hyaline droplet and necrotising or fibrinoid Amyloid nephrosis is a special type which is dealt with elsewhere (p 1131) Lipoid nephrosis has already been described under Type 2 nephritis and one form of necrotising nephrosis has been dealt with under Traumatic Anuria

Simple Nephrosis in which there is albuminous degeneration of the tubular epithelium occurs in febrile states and toxæmias From the renal point of view it is of no clinical significance except that mild albuminuria results Sometimes heavy albuminuria is produced for example in hepatic failure due to acute yellow atrophy or Weil s disease nitrogen retention may develop in such patients but is probably extrarenal in origin The term hepato renal syndrome has no specific meaning but is sometimes used for this combination of liver disease and renal tubular nephrosis

Mercurial Nephrosis is a typical example of severe tubular degeneration associated with chemical poisoning Ingestion of mercuric salts or even therapeutic use of mercurial lotions may in patients with idiosyncrasy produce fatty hyaline droplet and fibrinoid necrosis of the tubular epithelium which later *undergoes calcification*

Oliguria and hæmaturia are produced, along with other manifestations of mercurial intoxication and fatal uræmia may result In its clinical course and possibly in the development of the lesion this type of nephrosis is allied to that occurring in traumatic anuria There is some evidence that organic mercurial diuretics may damage the renal tubules, but it is extremely rare Bismuth poisoning may produce a similar picture to mercurial nephrosis but the renal damage is less severe Other chemical poisons which affect the kidney are carbon tetrachloride and phosphorus, they cause severe fatty degeneration of the tubules but the whole nephron is probably affected since fatal uræmia may occur

ECLAMPTIC NEPHROSIS —In fatal eclampsia severe tubular damage including fatty and hyaline droplet degeneration is found post mortem Although this is referred to as a 'toxæmia of pregnancy" it is more probable that the lesion is an acute ischæmic one comparable to that seen in malignant hypertension or traumatic anuria These changes like other tubular degenerative lesions, are difficult to relate to the clinical features and it is doubtful whether chronic renal damage results from this form of nephrosis Persistent hypertension and albuminuria following so called toxæmia of pregnancy usually indicate pre existing renal disease or hypertension Any effect cyesis may have on the course of these disorders is probably due to exacerbation of the hypertension which so frequently occurs about the middle of pregnancy

BILATERAL CORTICAL NECROSIS is a rare renal complication of pregnancy Although it occasionally occurs in male subjects without any obvious cause it may result from chemical poisoning or severe infections such as malaria In pregnancy it is usually associated with eclampsia or retro placental hæmorrhage Its pathogenesis is probably related to that of acute tubular necrosis (traumatic anuria) The clinical picture is one of severe abdominal pain and anuria leading to rapidly fatal uræmia without hypertension

OTHER FORMS OF NEPHROSIS —Tubular degeneration occurs in gout secondary to deposits of sodium biurate crystals in the interstitial tissue The common renal complication of gout is however, a chronic 'interstitial nephritis' probably due to associated essential hypertension

Myelomatosis is not infrequently complicated by severe renal damage The picture is often a mixed one due to ascending nephritis or ischæmic changes There is however a specific lesion in myelomatosis consisting of tubular atrophy consequent on the formation of obstructive casts which are in some way related to Bence Jones protein The glomeruli in such kidneys may be remarkably normal

NEPHROCALCINOSIS —It has already been stated that calcification of the tubular epithelium may follow necrotic changes such as result from mercury poisoning Similar epithelial calcification may be a late sequel of alkalosis due to severe vomiting or may follow traumatic anuria sulphonamide anuria and myelomatosis An entirely different type of nephrocalcinosis so called metastatic calcification occurs in hyper parathyroidism large interstitial deposits being formed Still another form is that occurring in hyperchloræmic acidosis in children in which the primary defect is a failure of the proximal tubule to reabsorb bicarbonate

CONGENITAL ABNORMALITIES OF THE KIDNEY

Many errors of development resulting in abnormalities of the shape or position of otherwise normal kidneys are of little clinical importance They are unlikely to give rise to symptoms or to progressive renal impairment although there is evidence that such kidneys have an increased tendency to infection Maldevelopment of the kidneys leading to insufficient functioning nephrons may without added infection lead to renal failure The pathological differentiation of such kidneys from those which are contracted as a result of chronic atrophic pyelonephritis or of vascular or ureteric occlusion early in life, may be extremely difficult if not impossible The

recognition of a congenitally absent or insufficient kidney is essential when nephrectomy is being considered as treatment of disease in the opposite kidney

RENAL AGENESIA —Agenesia implies the complete absence of a kidney Bilateral agenesia is of course incompatible with survival

RENAL APLASIA —An aplastic kidney contains no renal tissue capable of normal function Glomerular and tubular elements are contained perhaps with cysts within a dense stroma of fibrous tissue and scanty smooth muscle and the ureter is often not patent Owing to the difficulty of distinguishing such anomalous structures from secondarily contracted kidneys there is a lack of evidence whether they can be responsible for the development of hypertension

RENAL HYPOPLASIA —Truly hypoplastic kidneys contain virtually normal nephrons in markedly reduced numbers They are miniatures with reduced function commensurate with their size and are therefore unable to maintain life indefinitely if the condition is bilateral The renal failure which develops is analogous to that occurring in experimental animals in which a large part of the renal tissue has been removed Histologically hypertrophy of the individual nephrons and tubular dilatation are found

Hypoplasia may be one cause of the so called Rose Bradford kidneys in children or young adults pyelonephritis or glomerulo nephritis contributing to the picture of gross renal contraction in which areas of hypertrophied elements alternate with dense interstitial fibrosis A closely related group of very contracted kidneys is characterised by idiopathic dilatation of the urinary tract The condition may be unilateral or bilateral and the bladder may be dilated No organic cause of obstruction is found in the majority of these cases but chronic pyelonephritis is an invariable complication It is possible also that Rose Bradford kidneys may result from ascending infection of normal kidneys in early childhood or *in utero* In all these groups of gross renal contraction renal failure is prolonged and the symptoms of polyuria and polydipsia are particularly prominent Osteodystrophy (renal rickets and dwarfism) may occur in association with phosphate retention acidosis parathyroid hyperplasia and metastatic calcification Hypertension is infrequent whilst very occasionally hypotension is associated with sodium depletion due to chronic acidosis

CONGENITAL POLYCYSTIC DISEASE —This condition is described on p 1146

LARDACEOUS DISEASE

Synonyms —Amyloid or Waxy Kidney

Definition —A pathological condition in which the blood vessels of the kidney and in more advanced cases the tunica of the tubules and the interstitial tissue also are the seat of waxy degeneration

Ætiology —This affection is now rarely met with It attacks men more than women and although occasionally seen in children it is more likely to occur in adolescence and earlier adult life being uncommon after 50 years of age It is usually due to chronic suppuration especially in bone chronic tuberculosis and syphilis It rarely occurs in other chronic infections but it has been described in severe rheumatic heart disease and a certain amount of amyloid change has sometimes been found post mortem in patients suffering from chronic cardio vascular disease and chronic nephritis in the absence of chronic suppuration As it is a degenerative change it has however more affinity with nephrosis than with nephritis

Pathology —Amyloid material or lardacein is a product of protein degeneration and consists of protein linked with chondroitin sulphuric acid The latter substance is a normal constituent of elastic tissue and cartilage In uncomplicated cases the affected kidney has the appearance of a large white kidney with a smooth surface and a capsule that strips easily The organ is firmer than it otherwise would be

On section the cortex is thicker than normal and has a yellowish white appearance the glomeruli may be visible as minute translucent spots The pyramids are dark red in contrast to the pale cortex If a solution of iodine in potassium iodide is poured over the surface, some of the glomeruli stand out as mahogany brown spots and the vasa recta as brown streaks In histological preparations stained with methyl violet amyloid material takes a pink colour The disease tends to appear first in the capillaries of some glomeruli while others are normal and its incidence is often partial within a single glomerulus The afferent arterioles vasa recta and capillary plexus are next affected, in more advanced cases there is amyloid degeneration of the tunica propria of the tubules with amyloid deposits in the interstitial tissue In most cases there is an associated nephritis The kidney lesion is generally the most striking part of a widespread lardaceous degeneration which also involves the liver spleen and intestine less commonly the blood vessels of the thyroid suprarenals pancreas, heart and brain may be affected as well Occasionally only the kidney is implicated

Symptoms —The onset is insidious and the symptoms are not likely to occur unless chronic suppuration has existed for at least 3 months

The urine is copious of low specific gravity (1 003 to 1 010) The amount of albumin is variable when abundant hypoproteinæmia may result. The amount of urine and its specific gravity may also be affected by the presence and degree of coincident nephritis and the state of the heart Hyaline and granular casts are present in the urine casts staining brown with iodine are not evidence of amyloid disease and may occur in other diseases of the kidneys True waxy casts are not found In later stages there is œdema with diminished excretion of urine The blood pressure is not raised, nor is the left ventricle hypertrophied unless there is coexistent chronic nephritis

Diagnosis —The condition must be distinguished chiefly from Type 2 nephritis The diagnosis of amyloid disease is made (1) when there is a sufficient cause in the past history or present condition namely chronic suppuration or syphilis, (2) on signs of lardaceous disease in other organs such as enlargement of the liver or spleen and diarrhœa (3) on confirmatory evidence from special tests The Congo Red test is based on absorption of the dye by amyloid material and its consequent removal from the blood stream and failure to appear in the urine after intravenous injection of a known quantity of dye The test is positive in 80 to 90 per cent of cases When it is essential to be certain of the diagnosis (*e g* when a decision on surgical treatment of the primary infection must be made) drill biopsy of the liver will afford histological proof

Course and Prognosis —This depends on that of the primary cause If the latter is unchecked the disease is slowly progressive and death occurs from exhaustion due to the original disease or from uræmia Where the original disease can be cured recovery may occur Complete recovery of the kidneys is less likely than is recovery of the liver spleen and intestines This is probably due to associated nephritis

Treatment —The treatment is that of the original disease In suppuration of the bones or joints empyema etc it is surgical but it must be recognised that in advanced cases surgical treatment may be too late even though it is successful in eradicating the septic focus In all cases fresh air and sunlight and a nourishing diet are essential Iron and cod liver oil should be given Cases of syphilitic origin should be treated with appropriate antisyphilitic therapy

PYELITIS

Definition —Pyelitis is inflammation of the renal pelvis When complicated by nephritis the condition is termed pyelonephritis

Ætiology—Most cases are due to a blood borne infection of the renal pelvis The pelvis may also be involved by ascending infections—(*a*) via the lumen of the ureter when there is ureteral obstruction it is probable that infection does not spread by this channel when the lumen is normally patent (*b*) By way of the peri ureteral lymphatics from local foci in lower parts of the urinary tract such as the bladder urethra prostate seminal vesicles and epididymis Lastly there is the possibility of direct spread of infection from the bowel and by cross lymphatic channels from one kidney to the other In those cases in which a pyelitis occurs secondary to appendicitis cholecystitis ulcerative colitis etc the spread of infection may be by the lymphatics or the blood stream

Pyelitis is more common in females than in males Its age incidence depends on the determining cause Thus it is common in female infants as a result perhaps of urethral infection to which they are more liable than male infants It is not an uncommon complication of pregnancy occurring especially in the fifth month of gestation It is common in males at a later age associated with enlarged prostate and cystitis

In general terms any injury or disease of the renal pelvis or any condition which interferes with the normal flow of urine may be the determining cause of pyelitis Thus it is a common complication of hydronephrosis from whatever cause It often complicates stone in a kidney, tuberculosis of the kidney and new growths of the renal pelvis

Pathology—The mucous membrane of the pelvis is swollen œdematous and hyperæmic and the submucous venules are engorged Where there is obstruction the pelvis is dilated and contains a slightly turbid or opalescent fluid In these circumstances the ureter above the obstruction is dilated and tortuous and its walls are thickened The kidney is swollen and pale, from cloudy swelling and in severe cases there may be multiple small abscesses in the renal parenchyma

Bact coli is by far the most common infecting micro organism Streptococci staphylococci gonococci and bacilli of the *Proteus* and typhoid groups may be found The infecting micro organism is readily recovered from the urine

Symptoms—The clinical types of pyelitis differ greatly from one another, and the condition may be responsible for an acute fulminating illness or for chronic malaise of indefinite nature

Local Symptoms—Pain is the most important especially as a diagnostic indication in acute cases It is a dull ache in the loin or flank at first slight and intermittent later or in other cases at once constant and sometimes intense Occasionally it takes the form of renal colic At its onset the pain may be diffuse and abdominal Increased frequency and urgency of micturition is the most common symptom There may be strangury

General Symptoms—In acute cases there may be sudden onset with rigors vomiting headache and the general constitutional disturbance of profound toxæmia These cases may simulate septicæmia (in fact there may be septicæmia) appendicitis or when associated with abdominal distension constipation and vomiting may even simulate intestinal obstruction In other cases with cerebral symptoms meningitis may at first be difficult to exclude

In subacute cases without marked pain or rigors there is general malaise fever anorexia wasting and a secondary anæmia associated with some degree of polymorphonuclear leucocytosis (white blood count=10 to 15 000)

In relapsing cases there are periods of exacerbation with acute symptoms and intervening periods of fair health or general malaise Fever is commonly present in acute cases with rigors it may rise to 105 or 106 F In general the temperature is irregular remittent or intermittent varying between 102 and 104 F in acute cases and 100 and 102 F in subacute cases The pulse is raised in proportion to the temperature and there is a corresponding slight increase in the respiration rate

Of other general symptoms constipation or diarrhœa frequently precedes the disease and constipation generally accompanies it Toxæmia is often marked

Deep tenderness on palpation of the renal region and the presence of infected urine are the diagnostic signs of the disease There is some degree of abdominal rigidity, and it may be possible to determine enlargement and tenderness of the kidney The urine is passed in small quantities at frequent intervals It has the usual characters of febrile urine and is turbid The turbidity or an opalescence is still present after filtration When an appreciable quantity of pus is present it settles at the bottom of a specimen glass in a thick whitish deposit Examination of the deposit (catheter specimen in women) shows pus cells and epithelial cells from the urinary tract There may be hæmaturia

Bacteriuria—In this condition bacteria are present in the urine in such quantity as to make it hazy to the naked eye but there is little or no inflammatory reaction in any part of the urinary tract Hence there are no localising symptoms and few pus cells The urine when freshly passed has a hazy appearance In a test tube, when the tube is rotated, the urine has a "satiny" appearance or shimmer It is not cleared by filtration It often has a fishy smell in *Bact coli* infection, and is ammoniacal in smell in *Proteus* infection Its reaction is acid unless due to staphylococcal or *Proteus* infection It generally contains a trace of albumin and often may contain a few white blood corpuscles and epithelial cells A catheter specimen grown in broth in dilutions of 1 ml, $\frac{1}{10}$ ml and $\frac{1}{100}$ ml urine in 10 ml broth gives a growth in all dilutions and in *Bact coli* infections there is generally a growth in greater dilutions Streptococcal and staphylococcal infections are less common but even when present they are easily overlooked because the streptococci and some forms of staphylococci are liable to be overgrown by the *Bact coli* on culture Thus an infection by *Streptococcus fæcalis* may be first recognised only after the *Bact coli* infection has been eradicated by treatment

Diagnosis—When there is fever and constitutional disturbance without localising signs or symptoms the differential diagnosis is from those diseases which come in their early phases under the category of indeterminate fever The diagnosis is established by examination of the urine Pyonephrosis is diagnosed by the presence of a renal swelling Calculus is recognised by its clinical features and by radiography Perinephric abscess in its early stages is not accompanied by pyuria or increased frequency of micturition Cystitis is generally afebrile and it is accompanied by suprapubic discomfort and pain, particularly at the end of micturition, the diagnosis can be established by cystoscopy Urethritis is recognised by local tenderness urethral discharge and the appearances on urethroscopy and prostatitis by swelling and tenderness on rectal examination

Prognosis—The usual outcome of uncomplicated pyelitis with efficient treatment is recovery in 5 to 10 days Efficient treatment depends on the use of the drug namely a sulphonamide or penicillin to which the infecting micro organisms are sensitive When these remedies fail streptomycin may be effective within 24 or 48 hours even in the presence of a complication such as one or more stones in the kidney These new remedies have greatly diminished the risk of ascending suppurative nephritis pyonephrosis or chronic pyelonephritis

Treatment—Prophylaxis is important in nurseries and children s hospitals since there is evidence of spread of infection via the urethra in females Here it is a question of cleanliness In general terms exposure to cold over fatigue and loose stools are to be avoided when there is susceptibility to *Bact coli* infection of the urinary tract

A patient suffering from an acute attack is treated with rest in bed, fluids in large quantity, bowel function is regulated and sufficient alkali is given by mouth to make the urine alkaline In order to avoid chill the patient is nursed between blankets Five to 6 pints of fluid are given in every 24 hours in the form of water

barley water imperial drink weak tea and thin soups Milk may be citrated and as the temperature subsides diet is increased by the addition of starch fruit and vegetables Bowels are emptied with an initial laxative followed by an enema if necessary After this the action of the bowels is regulated with paraffin magnesia or mild laxatives such as liquorice powder rhubarb or aloes It is important to avoid habitual loose stools because this predisposes to urinary infection A mixture containing 30 g each of potassium citrate and sodium bicarbonate is given 3 hourly until the urine is alkaline Every specimen of urine passed is tested with litmus paper When the urine is alkaline the mixture is given at 4 or 6 hourly intervals that is to say in sufficient quantity to keep every specimen of urine alkaline

The alkali treatment of *Bact coli* infections of the urinary tract is now only given in the initial stage of the more acute cases and even in these with increasing experience of the efficacy of sulphonamide drugs in the treatment of urinary infections one of these drugs is given as soon as the disease is diagnosed Sulphacetamide is the drug of choice for *Bact coli* infections because of its low renal toxicity It is readily absorbed rapidly eliminated and is very soluble (much more so than sulphadiazine) Hence a high urinary concentration can be obtained with a relatively low blood level In an acute case with high fever and a large fluid intake 1 g is given 4 hourly As soon as the temperature subsides and the fluid balance in the patient is restored to normal the dose of sulphacetamide is reduced to one tablet 4 hourly and at the same time the fluid intake is limited to 2 pints in 24 hours This treatment is given until the urine is perfectly clear when freshly passed it is then continued for a further 48 hours In a mild or chronic case the length of treatment is generally 5 to 6 days In an acute case it may be considerably longer Forty eight hours after the drug is stopped the urine is again examined bacteriologically If the urine is still infected the diagnosis should be reconsidered

In the first place the infection may be a complication of concealed disease of the urinary tract such as calculous disease tuberculosis neoplasm enlarged prostate with residual urine or hydronephrosis Chronic pyelonephritis especially if of long standing may resist sulphonamide therapy Rarely a persistent infection may be a complication of organic disease of the digestive tract such as chronic appendicitis especially if the right ureter is involved diverticulosis or even cholecystitis In any case of urinary infection that is resistant to treatment or presents any unusual symptom a detailed investigation of both urinary and digestive tracts is required in order to determine or exclude a change in structure which may be the underlying and determining cause of the urinary infection

In the second place when the *Bact coli* infection has been cleared by sulphonamide treatment a residual infection with *Str fæcalis* or staphylococcus may be found It is important to clear the urine of these residual infections because they may determine a return of *Bact coli* infection Mandelix may be used for *Str fæcalis* infection The routine is to give ammonium or calcium mandelate gr 45 in solution (2 g) with 2 oz of water four times in 24 hours Fluid intake is limited to 32 oz which together with the medicine makes a total intake of 2 pints Every specimen of urine passed is examined as to its *p*H which must be 5 to 5 1 and sufficient ammonium chloride is administered by mouth to produce the required urinary *p*H

Penicillin given intramuscularly is almost wholly excreted in the urine where a high concentration is therefore attained Penicillin is now used for staphylococcal *Str fæcalis* and *Proteus* infections of the urinary tract as also in the unusual cases in which the *Bact coli* is penicillin sensitive Penicillin has therefore displaced sulphathiazole in the treatment of staphylococcal infections and mandelic acid in the treatment of *Str fæcalis* infections An average dose is 20 000 units 6 hourly throughout the 24 hours It is probable that the most effective treatment for Gram negative bacillary infections of the urine will prove to be streptomycin given intramuscularly

4 hourly in a dose of 0 5 g, namely 3 g daily for 2 days With further experience smaller doses may be found effective and 2 days treatment may prove sufficient.

In the uncommon fulminating cases with unilateral suppurative nephritis, nephrectomy may save the patient s life

CHRONIC PYELONEPHRITIS

It has already been stated that infection may spread from the renal pelvis into the kidney substance and produce pyelonephritis The recognition of this extension is difficult in the early stages because renal involvement is focal so that the diagnostic signs of nephritis are absent In severe cases of pyelitis however, a slight degree of œdema and hypertension may be observed A further pointer to the diagnosis is the persistence of albuminuria when the pyelitis has been effectively treated and pus and organisms are no longer found in the urine In chronic pyelitis, particularly when there are recurrent attacks over a period of years, the presence of chronic pyelonephritis is strongly presumptive An acute ascending infection particularly when drainage is defective, as in neurogenic retention of urine, may lead to suppurative pyelonephritis with the formation of multiple small abscesses Fever and toxæmia are severe and in such cases pyuria may persist in spite of antibiotic therapy A particularly intense and often fatal type of suppurative pyelonephritis occurs in diabetes and especially in elderly patients extensive medullary necrosis may be produced (see p 1127)

The particular importance of chronic pyelonephritis lies in the fact that it may persist and progress after the pelvic inflammation has subsided Gradual destruction of the renal parenchyma continues over a period of many years, usually in the absence of symptoms and the clinical course resembles very closely that of chronic Type 1 nephritis The similarity is further enhanced by the observation that a large proportion of patients presenting with this condition in its late stages give no history of acute pyelitis The incidence of this form of the disease is much higher in women than in men which suggests that sub clinical pyelitis may possibly have occurred during pregnancy at some time in the past

Pathology—Pyelonephritis is an interstitial inflammation of the kidney which leads to focal scarring and destruction of nephrons extending upwards from the medulla to the cortex Involvement of the kidney may be irregular, so that scarring may be confined to a single area, or may involve broad zones throughout the substance of the kidney This leads to the characteristic rat bitten appearance of the outer surface which is deformed by broad sunken scars While both kidneys may be involved to a similar extent, pyelonephritis is usually more marked in one kidney than in the other and there may be gross inequality in size Not infrequently one kidney alone is involved, the other showing compensatory hypertrophy It is highly probable that local obstructive lesions such as have been discussed under acute pyelitis are responsible for this uneven distribution Obstruction is also indicated by the presence of some degree of hydronephrosis although this may be slight Microscopically there is in many cases little evidence of active pyelitis but some degree of sub pelvic fibrosis is usually seen In the renal substance areas of scarring with dense round cell infiltration alternate with normal kidney tissue In the fibrotic zones the tubules are atrophied and characteristically groups of surviving tubules are seen in the cortex distended with hyaline material and presenting an appearance resembling thyroid tissue The glomeruli in the affected zones show ischæmic atrophy with hyaline thickening of Bowman s capsule aggregates of completely hyalinised glomeruli in the shrunken areas of the cortex are typical Occasionally glomeruli in the less affected areas show great dilatation and wavy distortion of Bowman s capsule the capsular space being filled with albuminous material In severely scarred kidneys

medium and large arteries are often prominent and show obliterative endarteritis Arteriolar changes are inconspicuous except in those rare cases which are complicated by malignant hypertension

Symptoms—There may be no symptoms in chronic pyelonephritis until attention is drawn to the condition by the development of uræmia or hypertension Alternatively there may be recurrent attacks of pyelitis or cystitis High blood pressure is not a common or prominent feature of chronic pyelonephritis nevertheless in some cases severe hypertension is observed and may progress to the malignant phase This complication is occasionally seen in unilateral disease It is difficult to say why only a minority of patients with pyelonephritis develop hypertension but there is a possibility that some other factor such as a congenital obstructive lesion of the kidney or even a constitutional tendency to hypertension may be responsible Albuminuria is usually present throughout the course of pyelonephritis the urine may also contain pus and bacteria but in many cases the ascending infection has resolved and pyuria is absent occasionally the urine may even be free from albumin A diagnosis of essential hypertension is then likely to be made and the underlying condition is only revealed when intravenous pyelography shows distortion of the renal calyces or evidence of renal contraction In the absence of hypertension uræmia may be so protracted in chronic pyelonephritis that osteodystrophy with metastatic calcification occurs In very rare cases chronic acidosis leads to severe sodium depletion and hypotension (so called salt losing nephritis) so that the clinical picture may closely resemble Addison s disease

Diagnosis—Persistent albuminuria associated with renal impairment with a past history of attacks of pyelitis will suggest the diagnosis Many patients with other forms of Bright s disease develop urinary tract infection however so that there will often be an element of doubt In the late stages the presence of uræmia with little or no hypertension should bring to mind the possibility of chronic pyelonephritis Intravenous pyelography should not be carried out if there is impaired concentrating power since concentration of the radio opaque solution is also defective Retrograde pyelography may show distortion of the renal calyces but this investigation is hardly justified in the presence of renal insufficiency

Prognosis—This depends on the extent of the lesion *i e* whether it is unilateral or bilateral and on the effectiveness with which active urinary tract infection can be controlled In established bilateral disease progress is very slow largely due to the absence of severe hypertension and the patient may continue in good health for 10 or 20 years before uræmia develops Even the stage of renal insufficiency tends to be protracted and consequently a long period of ill health must be expected in the later stages of the disease

Treatment—Active infection of the urinary tract should be treated as described under pyelitis Nephrectomy should be considered in unilateral pyelonephritis and particularly if hypertension is present Many cases have been reported where nephrectomy has been a life saving measure after the hypertension had entered the malignant phase *i e* when *papillœdema had developed* When renal failure develops treatment is that described for the corresponding stage of chronic Type 1 nephritis

PERINEPHRITIS AND PERINEPHRIC ABSCESS

Suppurative perinephritis may be due to blood stream infection when the invading organism is usually *Staphylococcus pyogenes* or it may arise from direct extension of local suppuration the invading organism being a member of the coliform group or other bowel pathogen

Ætiology and Pathology—Blood stream infection may follow injury, but more

frequently results from boils carbuncles and tonsillitis or complicates an acute specific fever J Koch has shown experimentally that intravenous injection of staphylococci is followed by their excretion in the urine after an interval of 4 to 6 hours In the process of excretion, according to Koch they may give rise to multiple cortical abscesses, cylindrical medullary abscesses, or, passing along the cortical lymphatics may gain access to the perinephric tissues and there cause abscess formation In these circumstances perinephric abscess is an example of staphylococcal pyæmia with single metastatic abscess formation Perinephritis by direct extension may complicate suppuration in the neighbouring organs, such as the kidney liver gall bladder or appendix It may be secondary to caries of the spine In other cases the infection may be carried by lymphatics from a focus in or around the bladder, rectum or female pelvic organs

Symptoms —The onset is generally gradual It is characterised by fever and malaise as in typhoid fever There may be no local symptoms for the first 7 to 14 days and during this period there is increasing toxæmia general abdominal discomfort or pain slight fullness and resistance, with deep tenderness in the affected loin As the abscess forms, pain and tenderness increase, there is induration and later, redness of the skin and œdema in the lumbar region The tumour first tends to spread backwards, obliterating the normal hollow in the loin and then as pus collects it may spread forwards forming a tender tumour palpable from the front In its relations to the colon it resembles a renal tumour, but does not move with respiration There is resistance or rigidity of the abdominal wall on the affected side There is an increasing polymorphonuclear leucocytosis up to 20 000 or even 40 000 *The urine is febrile in character, containing a trace of albumin and perhaps* a few white blood corpuscles, it does not contain pus, unless the kidney itself is involved, but hæmaturia may occur In some cases the disease runs an acute course and there may be rigors at an early stage

Diagnosis —Before localising signs appear the disease may be mistaken for typhoid fever, malaria or septic endocarditis The blood examination is important for the purpose of excluding malarial parasites leucocytosis is against typhoid fever and when above 15,000 is in general against infective endocarditis Absence of agglutination of micro organisms of the typhoid group is further evidence

When the tumour exists it has to be distinguished from a renal tumour or pyonephrosis Renal and adrenal growths may be accompanied by fever but do not usually give the general symptoms of suppuration they tend to extend forwards rather than backwards and induration of the tissues is absent Pyonephrosis causes symptoms of suppuration and a tender swelling but the tumour is circumscribed moves with respiration and does not cause any bulging in the lumbar region Pyuria is usually present

The diagnosis from caries of the spine, hip disease and even of myositis as distinct from perinephritis may be difficult Since perinephritis in itself induces lumbar rigidity and some degree of scoliosis radiographic examination may be required to exclude caries of the spine This investigation is also important since a diagnostic radiological sign of perinephric abscess is obliteration of the psoas shadow on the affected side Hip joint disease is excluded by absence of local tenderness and by the freedom of flexion and rotation of the thigh

Course —When the condition is simply associated with chronic nephritis it has no separate significance When it proceeds to suppuration the abscess may rupture into the peritoneum, colon or pleura, or on to the surface, unless the abscess is opened and drained

Treatment —The patient is treated at rest in bed and given penicillin—30 000 units 4-hourly Alternatively, sulphathiazole is prescribed namely an initial dose of 2 g followed by 1 g 4 hourly Fomentations or a kaolin poultice are applied to the loin Aspirin is given to relieve pain *If there is evidence of abscess formation*

an operation is performed and the pus evacuated penicillin being instilled into the abscess cavity

TUBERCULOSIS OF THE KIDNEY

Small grey tubercles are frequently found scattered through the kidneys in persons who die of acute miliary tuberculosis the kidney disease however scarcely affects the clinical aspect of the case and this form of renal tuberculosis will not be considered here Further in patients who die of pulmonary tuberculosis it is not uncommon to find tuberculous foci in the kidneys post mortem although there was no indication of their presence during life

Clinical renal tuberculosis is either the fibro caseating form of the disease or it is tuberculous hydronephrosis In either case the tuberculous infection is generally primary in the kidney in so far as its clinical expression is concerned

Ætiology—It is more common in women than men The maximum age incidence is in the third and fourth decades the disease is uncommon in the young and rare in the old At an early stage the disease is unilateral In the majority of cases the tubercle bacilli are carried to the kidney by the blood stream from a tuberculous focus such as a caseating lymph gland Recent experimental work has shown that bacteria do not ascend in the lumen of the ureter unless it is diseased when the infection may spread by direct extension in its walls Infection may also reach the kidney via the lymphatics in a proportion of cases The path of infection is by way of the ureteric lymphatics and it is probable that in pelvic tuberculosis for example tuberculous prostatitis may spread to the kidney by this route There is also reason to think that tubercle bacilli from a diseased kidney may infect the opposite healthy kidney by the same lymphatic path the bacilli first travelling in the urine and walls of the ureter from the diseased kidney and causing disease of the bladder and then travelling from the bladder by way of the ureteric lymphatics to the sound kidney On the other hand there is a shorter path for infection from one kidney to another by the para aortic lymphatic system Since the disease in the other kidney takes the same anatomical form as it originally had in the kidney first affected it is probable that, if the first is due to a blood borne infection so is the second Vesical tuberculosis is as a rule secondary to infection elsewhere in the urino genital system commonly in the kidneys

Pathology—The initial lesion is in the cortex or one of the pyramids and it consists of one or more tubercles The morbid process spreads by destruction of kidney tissue there is caseation in the centre of the lesion inflammatory reaction with intense small cell infiltration giant cell formation and more or less fibrosis at the periphery The lesion also spreads by the deposition of tubercles at a distance these are scattered through the cortex singly or in groups Extension through the capsule is uncommon but extension to the renal pelvis is frequent Complete destruction of one or more pyramids may occur or the disease may spread and involve one or more calyces or the entire pelvis The resulting infiltration and cicatricial contraction may lead to hydro or pyonephrosis The disease tends to extend down the ureter and the bladder is commonly infected at an early stage Secondary infections may lead to metastatic abscesses in the kidneys and ultimately to destruction of the whole organ

Symptoms—Frequency of micturition is often the earliest symptom it is first noticed by day and later at night Urgency and painful micturition develop next and are due to tuberculous cystitis The urine may show no other abnormality than a trace of albumin at an early stage characteristically it is pale and a little turbid from the presence of pus it is acid in reaction it may contain a few renal cells and it is sterile on culture By appropriate staining tubercle bacilli may be demonstrated

in the centrifugal deposit Hæmaturia may be the first symptom or the disease may develop insidiously with lumbar pain On examination the kidney is sometimes enlarged and it may be hard and irregular, it is often tender Tenderness along the course of the ureter or thickening of the ureter, as determined by abdominal or rectal examination, is of great importance The rest of the urino genital system requires close examination, this should include cystoscopy and in some cases ureteral catheterisation Radiographic examination of the abdomen may reveal calcified tuberculosis of the kidneys or lymph glands and it may be required in the differential diagnosis from renal calculus Finally, a careful review of the patient s history and present condition for evidence of a chronic bacterial toxæmia or of tuberculous infection elsewhere must be made

Diagnosis—The presence of tubercle bacilli in the urine whether determined by microscopic examination of the stained deposit or by guinea pig inoculation is not absolute proof of renal tuberculosis, because the bacilli may be excreted by a healthy kidney or they may come from some other part of the urinary tract Nevertheless the demonstration of tubercle bacilli in the urine is of the first importance in a doubtful case and the diagnosis may be established by cystoscopy The cases which require most careful examination are those with an atypical onset, such as massive hæmaturia, and those in which there is a gross secondary infection when first seen The possibility of renal tuberculosis must always be borne in mind in hydro and pyonephrosis The differential diagnosis from simple albuminuria and the several forms of Bright s disease is made on the presence of pyuria and the absence of signs and symptoms of chronic nephritis

Course and Prognosis—The onset is insidious and the course progressive Natural recovery is hardly known though occasionally an unsuspected caseous kidney may be found at autopsy in patients dying of other diseases The disease runs an uncertain course having a duration of a few years up to 10 or 12 years from the date of diagnosis Death results from tuberculous toxæmia, secondary infection or failure of renal function

Treatment—When the disease is unilateral the kidney should be removed but nephrectomy is rarely justified if the other kidney is involved In any case the patient s health and resistance should be raised to the utmost by rest fresh air and good food on the general lines of treatment of tuberculosis of the lungs Therapeutic trials of the specific remedies against tuberculosis, streptomycin with isoniazid or sodium amino salicylate, have shown that renal tuberculosis is more resistant to treatment than other forms of the infection and further experience is required before their effectiveness can be assessed

RENAL CALCULI (NEPHROLITHIASIS)

Renal calculi may be composed of calcium oxalate or phosphate, uric acid urates phosphates, cystine or of a mixture of these

Ætiology—All these materials are sparingly soluble in water and their solubility in urine is dependent on (i) its *p*H If this stands at 5 uric acid is precipitated while phosphates and carbonates are deposited at *p*H about 8, the others at some intermediate point (ii) On the presence of urea which renders both uric acid and oxalates more soluble (iii) The protective action of certain non albuminous colloids If these become coagulated their protective influence is lost Any condition which interferes with the free flow of urine and so leads to stagnation predisposes to and may determine the formation of calculi Thus prolonged recumbency as after fracture of the femur may determine calculus formation due to stagnation in the dorsal portion of the calyces Infection of the urinary tract may be secondary to the calculus but it is also a cause of calculus formation by altering the colloid content of the urine or

by its effect on the pH of the urine Metabolic disorders may be a factor in some cases as for instance in the uric acid stones which may occur in young children Hyperparathyroidism leads to excessive mobilisation of calcium from the bones and this is followed by ' metastatic calcification in various tissues including the kidneys Hot climates tend to favour stone formation owing to concentration of the urine due to excessive sweating

Pathology —The pure oxalate stone is very hard mulberry shaped stained by altered blood and varies in size from that of a mere granule to that of a walnut If it is encrusted with uric acid it becomes brown and in form a coral shaped mass representing a cast of the renal pelvis and calices Phosphatic stones are generally smooth and white A cystine stone is hard oval light amber or greenish in colour with a glistening surface Other forms are rare If the stone remains in the renal pelvis it may (1) by gradually increasing in size lead to the atrophy of the renal tissue (2) by eroding the capsule of the kidney produce a fistula into the perinephric tissues resulting in a perinephric abscess (3) by obstructing the outflow of urine cause hydronephrosis or more frequently pyonephrosis If it passes into the ureter it may become impacted in this way again exciting hydronephrosis or pyonephrosis or if it obstructs the ureter completely, may produce atrophy of the kidney If it causes ulceration of the ureter this may be followed by stenosis If it passes into the bladder it is very likely to excite ammoniacal decomposition and thus become encrusted with phosphates

Symptoms —A stone may remain latent in the kidney without causing any symptoms More usually it causes pain particularly on any jolting movement This is occasionally referred to the opposite side a point to be borne in mind when considering operation A bout of pain may be accompanied by hæmaturia and there may be albuminuria for some days afterwards A small oxalate stone may produce more pain than a large uratic stone because of its hardness and roughness A large branched uratic stone occasionally causes profuse hæmaturia without any pain The results of renal calculi may be classified as (*a*) mechanical (*b*) septic Under the first heading come colic hæmaturia anuria hydronephrosis under the second pyelitis perinephric abscess pyonephrosis

Renal colic is the most severe and distressing manifestation of calculus It is particularly likely to be started by riding on a horse or in a jolting vehicle which causes the calculus to engage in the entrance to the ureter Violent paroxysms of pain then occur radiating along the course of the genito crural nerve down into the groin and testis which becomes retracted in the scrotum The pain is also felt in the loin and the muscles overlying the kidney become rigid Vomiting and sweating are common The patient is unable to keep still and rolls about or gets on to his hands and knees calling out with each paroxysm He becomes pale and his pulse increases in frequency and the temperature is apt to rise During or after the attack there is usually some hæmaturia and crystals may be found in the urine The attack may last several hours and then end as abruptly as it began Anuria is a serious symptom and implies that the ureter is completely blocked and the other kidney is either diseased or its secretion reflexly inhibited Occasionally both ureters may be blocked by calculi Symptoms referred to the bladder prostate or seminal vesicles do not occur until the stone reaches the bladder or the lower end of the ureter

Diagnosis —The occurrence of renal colic and hæmaturia suggests stone but these symptoms may be produced by the passage of a blood clot from renal neoplasm or by acute pyelitis especially in a movable kidney Ordinary examination of the abdomen reveals nothing beyond lumbar tenderness in uncomplicated cases Radiographic examination is of great value Oxalate stones are the easiest to detect by this method as even when small they throw a dense shadow This is fortunate since oxalate stones are the commonest Pure uratic stones may not be detected unless they are large Cystine stones throw a less dense shadow than calcium oxalate stones

Calcareous abdominal glands and phleboliths may be mistaken for calculi on radiographic examination In doubtful cases, pyelography, intravenous or instrumental should be done A radiograph of the pelvis should never be omitted, since a stone may have passed down to this region Attacks of pain and hæmaturia with the presence of calcium oxalate crystals in the urine but with a negative radiographic examination are probably due to crises of oxaluria Appendicular colic may simulate renal colic, but the point of maximum tenderness is different

Prognosis —As long as there is no serious destruction of kidney substance or septic complication the outlook as to life is good, if treatment is adequate Attacks of renal colic may occur from time to time with great suffering and even after stones have been removed by operation they may form again Occasionally stones may be followed by chronic pyelonephritis with its usual consequences

Treatment —Indications for treatment are provided by the ætiological factors already discussed In any case of long recumbency the patient must lie on his face several times in the 24 hours Any condition of stasis in the urinary tract will be dealt with as far as is possible The treatment of infected urine is described under pyelitis If a renal calculus is present and this is confirmed by radiography removal by operation is indicated The following points however, are generally contraindications for operation (i) large bilateral stones, (ii) stones which are only the size of a pea or smaller, unless there is severe pain extensive absorption of renal substance causing toxic symptoms, or obstruction to the outflow of urine If a small stone is not passed as a result of medical treatment, its removal by operation should be seriously considered, (iii) in some patients small calculi are repeatedly formed and passed In these cases operation is better postponed because of the likelihood of recurrence If the diagnosis is uncertain or operation is refused or postponed or considered inadvisable because of the patient's general condition the treatment appropriate to the deposit found in the urine should be continued Violent exercise and jolting movements should be avoided Small stones can often be got rid of by giving the patient 5 to 10 minims of tincture of belladonna with gr 10 of potassium citrate every 4 hours for a few days, and directing that 5 pints of water should be taken in the 24 hours For the symptomatic relief of pain aspirin in 10 grain doses hot baths and kaolin poultice (antiphlogistine) may be of service Morphine should be avoided in the treatment of chronic renal pain on account of the danger of establishing a habit

For an attack of renal colic morphine gr $\frac{1}{6}$–$\frac{1}{4}$ together with atropine sulphate gr $\frac{1}{100}$ should be given hypodermically The anti spasmodic effect of the atropine aids the onward passage of the stone while the morphine relieves the pain If morphine be given alone, the pain is apt to recur as soon as its anodyne effect passes off Ten minims of tincture of belladonna should then be given in an ounce of water every 3 or 4 hours with abundant fluids, as described above until the pupils are dilated and the face rather flushed Hot applications to the loins or hot baths may help to relax spasm After the paroxysm is over a radiograph should be taken to locate the stone if it has not been passed

HYDRONEPHROSIS

Definition —A condition in which the pelvis and calyces of the kidney are distended by the accumulation of non infected urine due to ureteral or urethral obstruction

Ætiology —CONGENITAL —The condition may be congenital due to an abnormality of the ureter or urethra other congenital defects may be present The ureteral stricture is commonly found at the exit of the ureter from the pelvis of the kidney or near its entrance into the bladder Congenital narrowing of the ureter is much

more common than was previously recognised Other congenital causes are a faulty connection of the ureter to the pelvis of the kidney or an aberrant renal artery Hydro nephrosis is sometimes found post mortem in infants and children without evidence of obstruction to the outflow of urine In these cases the condition is presumed to be due to a neuro muscular inco ordination comparable to congenital hypertrophic stenosis of the pylorus

ACQUIRED —It is more common in females than in males and the maximum age incidence in 74 cases collected by Herringham was between the third and sixth decade

(*a*) *Bilateral* hydronephrosis results from stricture of the urethra phimosis enlarged prostate obstruction within the bladder or from a pelvic tumour the last named is the commonest cause

(*b*) *Unilateral* hydronephrosis is due to ureteral obstruction from—

1 Obstruction of the lumen by a stone growth or blood clot
2 Stricture of the ureter following ureteritis
3 Pressure from without due to growths
4 Torsion of the ureter by displacement of a movable kidney It is also thought that chronic prostatitis or cervicitis may cause sufficient inflammation to produce some dilatation of the kidney pelvis and upper ureter which lengthens and thus kinks the latter

Pathology —Two types of hydronephrosis are recognised namely the pelvic type due to upper urinary tract obstruction and the renal type from obstruction to the lower tract In the former the pelvis of the kidney is dilated and there is less absorption of renal parenchyma in the calyces In the latter the calyces are more dilated and there is considerable destruction of kidney substance

It is generally held that hydronephrosis results from intermittent obstruction It has been produced experimentally however by ligature of the ureter causing complete obstruction But complete obstruction is more usually followed by atrophy of the kidney

Symptoms —Many cases are latent and give rise to no symptoms The tumour may be discovered accidentally or there may be complaint of pain in the flank or back The onset is insidious

The symptoms by which a hydronephrosis is indicated are the presence of a renal tumour and complaint of an aching pain in the flank or back and sometimes polyuria or hæmaturia In intermittent hydronephrosis the tumour suddenly disappears with the passage of a large quantity of watery fluid after an interval the tumour gradually reappears and finally empties suddenly as before This sequence may be repeated at intervals Where true polyuria or hæmaturia occurs it is due to a coincident nephritis or pyelitis There may be acute exacerbations of the chronic pain with vomiting and collapse such attacks may accompany emptying of the hydronephrotic sac

Diagnosis —The condition especially when bilateral and unaccompanied by symptoms is generally overlooked In its most characteristic form where the hydro nephrosis is intermittent the diagnosis is readily made When the condition is apparent simply as a renal tumour the diagnosis from renal neoplasm (or retro peritoneal glands in a child) is difficult When the tumour is large it may be mistaken for an ovarian tumour A urinary infection is often the first sign of hydronephrosis The diagnosis can be established by intravenous pyelography supplemented if neces sary by instrumental pyelography Aspiration of the sac has occasionally been done for diagnostic purposes but surgical exploration is a safer measure Fluid from a hydronephrotic kidney is clear or slightly turbid it contains albumin and traces of urea and other urinary constituents in the deposits there are epithelial cells

Course —When unilateral hydronephrosis may never cause serious trouble and intermittent cases may persist for years In bilateral cases uræmia may supervene

Infection of the kidney is not uncommon, and may lead to acute pyonephrosis The sac may discharge spontaneously through the ureter, and the fluid never reaccumulate The sac may rupture into the peritoneum or rarely through the diaphragm into the lung Cases have occurred in which the ureter of the sound kidney has been blocked by a calculus

Prognosis—This depends on the cause of the hydronephrosis and the condition of the opposite kidney

Treatment—The first indication is to remove the cause A narrowing of the ureter, generally congenital, or stenosis at the ureteropelvic junction are especially important causes of hydronephrosis Whereas in the past slight cases of hydronephrosis were treated on general lines and nephrectomy was performed for large hydronephrotic kidneys nowadays slight cases of hydronephrosis are examined with the greatest care and surgical treatment is more often undertaken as a preventive measure An abdominal belt or nephropexy may prevent the development of hydronephrosis in a movable kidney When a hydronephrotic kidney is infected the infection should be eradicated and with modern methods of treatment (see treatment of pyelitis) this can sometimes be achieved

In unilateral hydronephrosis causing serious symptoms or of large size, a plastic operation or nephrectomy is advisable Since the state and function of the opposite kidney can be fairly accurately ascertained by pyelography and examination of a sample of urine obtained by ureteral catheterisation nephrectomy is a less serious risk than it was before these exact methods of diagnosis were available

In bilateral hydronephrosis the main indication is to remove the cause when possible and to adopt every measure that may aid in preventing infection of the urinary tract

PYONEPHROSIS

Definition—Distension of the renal pelvis with pus to an extent sufficient to cause a renal tumour

Ætiology—The affection is a sequela of pyelitis or hydronephrosis There are two main types namely tuberculous and pyogenic pyonephrosis The latter which is the commoner, is most frequently due to an impacted calculus

Symptoms—The patient is wasted toxic and febrile Rigors are common There is a renal tumour which is tender on palpation and moves to some extent with respiration Pyuria is present unless the ureter is completely obstructed

Diagnosis—The differential diagnosis from hydronephrosis is made from the presence of pyuria and of local and general symptoms of bacterial infection Perinephric abscess gives signs of a more diffuse swelling usually with œdema and redness of the surrounding skin and does not move with respiration

Treatment—In bilateral cases the treatment is palliative In unilateral cases nephrectomy is indicated if tests show that the other kidney is adequate

TUMOURS OF THE KIDNEY

BENIGN GROWTHS

These are of relatively slight importance

ADENOMATA are the most common occurring in the cortex or under the capsule They may be single or multiple multiple nodules commonly occur in sclerotic kidneys in old age They seldom attain any size

FIBROMATA are not uncommon as nodules sometimes multiple in the cortex or medulla LIPOMATA and ANGIOMATA are rare

MALIGNANT TUMOURS

DYSEMBRYOMATA —These tumours are found most commonly in children under 3 years and almost always under the age of 11 They are more often bilateral than carcinoma They consist of cells remaining at the embryonic level and failing to differentiate in any direction (Round celled Sarcoma) There is a stroma of undifferentiated fœtal connective tissue which resembles spindle celled sarcoma In some tumours some degree of differentiation may take place Thus these tumours may contain embryonic striped muscle primitive cartilage or nervous tissue and primitive poorly formed tubules can usually be found They are yellow and homo geneous on section

ADENOCARCINOMA OF RENAL TUBULES —The Grawitz tumour or hypernephroma is now recognised as an adenocarcinoma arising in tubular epithelium These tumours are single large well circumscribed and often surrounded by a capsule of compressed kidney tissue which is destroyed by pressure rather than by infiltration These tumours consist of solid anastomosing columns of cells Their blood supply consists of irregularly shaped lake like sinusoids which lie between the tubules of the growth in contradistinction to adenomata, which are composed of well formed tubules having well defined lumina and a simple capillary circulation Both in adenomata and adeno-carcinomata and especially in the latter the cells are infiltrated with a lipoid fat-glycogen complex (lipoid infiltration) which gives these tumours their peculiar yellow colour Recent and old hæmorrhage is commonly seen Cystic degeneration often occurs On section there is fine and coarse lobulation These tumours may spread along the renal veins into the inferior vena cava and to the pelvis of the kidney and perinephric tissues

Symptoms —1 Hæmaturia is the first symptom in more than 70 per cent of the cases It is much less frequent in children The blood is fluid or clotted and moulds of the pelvis or ureter may be passed The hæmaturia is spontaneous profuse and intermittent it is little influenced by rest nor is it provoked by exertion It may be the only evidence of a neoplasm and after lasting for a week or 14 days may cease leaving no further evidence of the growth until at some later date a tumour is felt The urine frequently contains albumin at intervals

2 Pain is uncertain It may be a dragging feeling or a constant ache The passage of clots may give rise to renal colic otherwise the hæmaturia is not accom panied by pain

3 The presence of a tumour is a most important sign It is felt on deep palpation bimanually It is first palpable below the ribs outside the rectus muscle as a solid swelling with rounded borders that moves with respiration It may be possible to define its upper border As the tumour increases it tends to go forward It may fill the hollow below the twelfth rib behind but does not cause a swelling in the back Large renal tumours cause asymmetry and bulging of the abdominal wall and marked displacement of neighbouring abdominal viscera On the right side the ascending colon lies in front on the left the last part of the transverse colon and the upper part of the descending colon the tumour is therefore resonant on percussion in front When the tumour is highly vascular pulsation is felt in it and a systolic bruit may be heard over it In later stages it is liable to become fixed by adhesions

4 Progressive emaciation is generally late It may be absent although the tumour is large

5 Metastases are sometimes the first sign of a renal neoplasm occurring in the lungs bones or brain Secondary deposits in the para aortic lymph glands may cause obstruction to the inferior vena cava or this may result from pressure of the tumour itself

Diagnosis —Diagnosis is made on the presence of hæmaturia with a tumour When hæmaturia occurs alone and other causes have been excluded by careful clinical

bacteriological and radiographic examination then a more detailed investigation of the urinary tract must be undertaken immediately This entails cystoscopy intravenous pyelography and on occasion retrograde pyelography When a tumour is the only sign an exploratory laparotomy is advised The tumour requires to be distinguished from splenomegaly, hepatomegaly and Riedel s lobe A renal tumour has not the definite edge characteristic of splenomegaly and enlargement of the liver Enlargement of the liver is not often a source of difficulty A Riedel s lobe is continuous with the liver, does not extend back into the loin and is dull on percussion Splenic tumours are recognised by the fact that they tend to occupy an oblique position in the abdomen by the presence of a notch and of a sharp inner margin, free movement with respiration and dullness to percussion

A differential diagnosis from retroperitoneal tumours including those of the suprarenal is not always possible though the suprarenal growths may sometimes be recognised by certain characteristic features Thus, there is the medullary sarcoma type described by Hutchison generally occurring in children characterised by metastases in the skull ecchymotic swelling of the eyelids papilloedema and severe anæmia, and the "infant Hercules" type of tumour of the adrenal cortex (see p 523)

Prognosis —The disease is almost invariably fatal Many die within 2 years, and the majority within 4 years, though exceptional cases of survival for 5 to 10 years after operation have been recorded

Treatment —*Surgical treatment alone holds out a prospect of cure* Symptomatic treatment includes the use of drugs for the relief of pain and the control of hæmaturia

CYSTS OF THE KIDNEY

SOLITARY CYSTS

These may occur in an otherwise normal organ They vary in size from very small cysts to tumours of considerable bulk They result from dilatation of an obstructed tubule and they may be congenital

MULTIPLE CYSTS

Multiple cysts of small size are commonly met with in sclerotic kidneys They result from chronic inflammatory changes that lead to obstruction of the tubules with subsequent dilatation There are also rare cases of multiple cysts of large size whose ætiology and course are little known

POLYCYSTIC DISEASE OF THE KIDNEYS

Definition —Polycystic kidneys appear as a massive conglomeration of cysts varying in size from a pin s head to a marble separated by dense strands of fibrous tissue in which little or no renal tissue is evident on naked eye examination

Ætiology and Pathology —The commonest age incidence is between 40 and 50 years they are relatively common in the decades preceding and following they may occur in infancy and childhood and of these a large proportion are in still born infants Those occurring in infants are congenital and other congenital abnormalities may be present The disease in adults is probably also congenital in origin In this case it must be progressive because the renal damage in the later stages is too severe to have been compatible with many years of active life In this connection it is noted that the disease is often found in more than one member of a family and in successive generations Its familial incidence congenital origin and association with cysts in

other organs especially the liver all suggest that this disease belongs to the group of congenital developmental errors

The organs are enlarged in size and weigh 20 to 30 oz each or even 3 to 4 lb They have been compared to a bunch of grapes in appearance The cysts project from the surface and form the mass of the organ They are lined by a layer of flat tened cells and are filled with fluid This fluid is clear or turbid limpid or viscid colourless or yellowish it is sometimes blood stained giving it a red purple or green colour Urea has been found in the fluid which may also contain fat globules cellular débris cholesterol and triple phosphate crystals On microscopic examination com pressed renal parenchyma is found in the septa between the cysts the tubules are distorted and exhibit varying degrees of atrophy degeneration and dilatation while the glomeruli show changes due to chronic ischæmic or hypertensive damage The blood vessels of the kidney undergo sclerotic changes there is increased fibrous connective tissue and small cell infiltration In some cases cysts are also found in the liver ovaries broad ligament uterus pancreas and spleen but they are rare in any other organ than the liver

Symptoms —The affection is nearly always bilateral When the tumours develop to large size in the fœtus difficulty in labour may result In the adult there may be no symptoms or any of the symptoms of chronic nephritis may develop and may terminate in uræmia cerebral hæmorrhage or cardiac failure General arterial disease with raised blood pressure and cardiac hypertrophy is commonly present on the other hand the condition may reach an advanced stage and fatal termination without appreciable cardiac hypertrophy In a third group the bilateral renal tumours are the most striking features associated with general malaise dull aching pain in the loins and recurrent hæmaturia The tumours are not tender and present the ordinary signs of renal tumours (*q v*) The urine is of low specific gravity and commonly contains a trace of albumin there may be polyuria

Diagnosis —The finding of albuminuria in association with large irregular bilateral renal enlargement should suggest polycystic disease Hydronephrosis pro duces a smooth rounded renal swelling Renal neoplasms other than sarcomata are nearly always unilateral The absence of fever and pyuria excludes bilateral pyo nephrosis Intravenous pyelography often shows characteristic ring shadows due to distortion of the calyces by the cysts

Course —This closely resembles that of chronic nephritis

Treatment —The treatment is that of chronic nephritis Operation is contra indicated since both kidneys are nearly always equally affected

OTHER FORMS OF CYSTIC DISEASE

Echinococcus cysts may occur in the kidney and the discharge of the daughter cysts has produced attacks of renal colic *Cystic degeneration of renal neoplasms* is described elsewhere

MOVABLE KIDNEY

Synonym —Nephroptosis

The kidney is normally held in place by the perirenal fat the renal vessels and the peritoneum stretched over it But this does not prevent a certain amount of respiratory excursion as may be seen either by radiographic examination or in the operating theatre The range of movement varies between 1 and 2 inches and is more marked on the right than the left side The term movable kidney should there- fore only be applied to cases where there is an excessive respiratory descent so that the upper as well as the lower pole can be felt or where the kidney can be moved

about by external manipulation As the kidney slips downwards the lower pole gradually passes towards the middle line, while the organ rotates slightly, causing the hilum to look somewhat upwards

Ætiology—Movable kidney is about seven times more common on the right than on the left side The ascending colon and the hepatic flexure lie on the inner aspect of the right kidney thus tending to drag it down when the bowel is loaded or dropped On the left side, on the other hand the strong costo colic fold suspends the splenic flexure much more securely while the descending colon lies to the outer side of the left kidney

The condition is much commoner in women than in men In men the kidney pouches are deep narrow and rapidly diminish in breadth from above downwards while in women they are much shallower and broader, and diminish only slightly in breadth from above downwards This natural difference is accentuated in the spare long waisted women with narrow loins who are recognised as specially liable to floating kidney

Pathology—Many reasons have been given for the occurrence of movable kidney, but few will stand investigation Wasting with loss of perirenal fat or loss of tone in the muscles of the abdominal wall have been held responsible but movable kidney is so common apart from such conditions that their importance is doubtful Glénard emphasised the frequency with which movable kidney is associated with a general visceroptosis indeed it is rare to find a movable kidney without coloptosis Movable kidney is the most obvious sign of visceroptosis because the organ is easily palpable

A serious sequel is the occasional occurrence of hydronephrosis produced by torsion of the ureter during the forward rotation of the organ or by its becoming kinked over the renal vessels If hydronephrosis occurs a subsequent infection may convert it into a pyonephrosis

Symptoms—There may be no symptoms at all and if the movable kidney is only discovered in the course of routine examination it is better not to tell the patient of its existence The commonest symptom is a constant dragging pain owing to traction on the renal plexus This most frequently first declares itself between 25 and 35 years of age A zone of hyperæsthesia corresponding to the distribution of the tenth thoracic segment may also be present More serious symptoms directly due to movable kidney are Dietl s crises but these are not common The attacks are characterised by severe pain radiating down the ureter and through to the back and may be accompanied by shivering nausea vomiting fever and collapse The urine is scanty and may contain blood Sometimes the pelvis of the kidney may become distended giving rise to an obvious increase in the size of the organ thus causing a tumour which is easily palpable and may be so large as to be obvious on abdominal inspection This may pass off later with abundant discharge of urine, showing that the crises are due to kinking and consequent partial obstruction of the ureter If repeated they may lead to hydronephrosis The other symptoms which have been attributed to floating kidney are really due to the associated visceroptosis (*q v*) A movable kidney usually feels larger than the normal excised organ This is because of the surrounding investments through which it is felt

Diagnosis—Usually this is obvious as the shape and mobility of the organ are so characteristic Occasionally a Riedel s lobe has been taken for movable kidney but the continuity of the former with the liver should prevent this mistake being made In the same way, a distended gall bladder is continuous with the liver and cannot be separated from it Moreover it is not nearly so movable and curves characteristically towards the umbilicus Carcinoma of the pylorus has offered difficulties in some cases examination of the stools for occult blood a test meal and radiographic examination will clear up the diagnosis Scybala near the flexures of the colon may be mistaken for floating kidney but their indefinite shape and inelasticity

generally help to distinguish them Their disappearance after a series of enemata will settle the question In one case a mesenteric cyst appeared closely to resemble a floating kidney

Prognosis —Apart from the development of hydronephrosis movable kidney does not tend to shorten life in any way It is doubtful whether a kidney once pro lapsed can ever maintain the normal position unaided

Treatment —Some cases call for no local treatment though the associated viscer optosis and neurasthenia will require attention If pain is felt the adoption for a short time of the knee elbow position or simply lying flat on the abdomen will help to replace the kidney and relieve the tension on the renal plexus If pain is at all frequent an abdominal support should be worn namely a corset especially designed to give support to the lower abdomen and increase the general intra abdominal pressure Kidney belts and special pads to support the movable kidney are no good Breathing exercises to develop the expansion of the lower thorax with exercises to improve the tone of the abdominal wall and general measures to improve muscle tone should be prescribed in all cases Treatment on these lines may make the wearing of a special corset unnecessary Operation should not be advised except for recurrent Dietl s crises or when there is evidence of hydronephrosis when nephropexy may be done But even this may not be successful, and ultimately nephrectomy may be required for the hydronephrosis

Treatment of Dietl s crises —The patient is put to bed and is advised to lie on his abdomen or try the effect of the knee elbow position Hot fomentations or a kaolin poultice are applied to the affected side A hypodermic injection of a quarter to one third of a grain of morphine may be required if the pain is severe Usually this is sufficient but should the attack last more than a few hours an attempt must be made, under an anæsthetic to rectify the position of the kidney by manipulation Naturally conditions are unfavourable for nephropexy during or immediately after a crisis because of the congested state of the organ

CLIFFORD WILSON

SECTION XV

DISEASES OF THE JOINTS, FIBROUS TISSUES AND MUSCLES

ARTHRITIS

THE diagnosis of 'arthritis' should be reserved for cases in which there are intrinsic pathological changes in a joint

The clinical conception of chronic arthritis is much simplified by modern classification which divides it into two clear cut *clinical* types, each of which presents distinctive features These are the rheumatoid arthritic type and the osteo arthritic type The features of the rheumatoid and osteo arthritic types of arthritis will be found under their respective headings below, and since the criteria of these types are clinical, this terminology can be correctly employed in those cases in which the ætiology remains obscure

The basic difference between these two types is that rheumatoid arthritis is a general disease in which the most obvious local effects fall upon the locomotor system, while osteo arthritis is a degenerative type of change which without affecting the patient s general health for various reasons becomes localised in certain joints

There are in addition certain cases which are referred to as 'mixed', in which the degenerative lesions of osteo arthritis become superimposed upon those of an inflammatory arthritis of the rheumatoid type

1 RHEUMATOID ARTHRITIS

Synonyms —Atrophic Arthritis Polyarthritis

Rheumatoid arthritis is a general progressive disease affecting principally the joints, which become swollen and painful If unchecked great destruction and deformity results

Ætiology —The malady is said to occur at least three times as frequently among females Women between the ages of 20 and 40 years are most commonly affected and the disease seldom commences after the menopause Predisposing factors exist *in many cases and include infection malnutrition and emotional shock* Focal infection may be present but this is not usually the main causative factor

Pathology —The pathological processes are inflammatory in nature The soft tissues and the white fibrous structures around the joints are the first to be affected The inflammation then spreads to the capsule and synovium and granulation tissue forms in the angle made by the articular cartilage with the synovium The latter then gradually extends inwards as a ring of pannus , covering and eventually replacing the articular cartilage As this happens on both articular surfaces the tendency is for them to adhere especially if the joint is immobilised for long periods and so fibrous ankylosis occurs which in some cases progresses to a bony ankylosis In some cases there is a marked tendency for the development of ganglia and cysts, which are generally in close association with joints or tendon sheaths

There are atrophic changes affecting the skin' subcutaneous tissues muscles ligaments joints and bones This latter condition of generalised osteoporosis shows

as the first *radiographic* evidence of the disease The peri articular swelling can also be seen in outline but actual joint destruction does not occur until considerably later Some degree of patchy recalcification may be observed when the progress of the disease is checked Osteophytes are never found in rheumatoid arthritis but in late cases very considerable disorganisation of the joints takes place and in these areas the bone sometimes gives the appearance of having been dissolved away

The chief pathological change in the blood is an increase in the sedimentation rate of the red blood cells This is an important index of activity and the response of a patient to treatment over a considerable period can be estimated with some accur acy by means of this together with clinical observation A secondary anæmia is usually present in the pre arthritic phase The glucose tolerance of the patient is generally found to be reduced in the active stages of the disease the albumin globulin ratio in the plasma is often reversed

Symptoms —There is in most cases a prodromal period during which the patient loses a considerable amount of weight and fatigue both mental and physical is a marked feature in nearly all cases There may be other symptoms such as paræsthesia Raynaud like phenomena irregular menstruation tachycardia sweating and a second ary anæmia Certain pioneer symptoms are not uncommon and it is of the utmost importance to recognise these amongst them is pain and tenderness of the heads of the metacarpal bones and especially of the second (Morton s disease) Inter mittent attacks of synovitis without apparent cause and affecting tendon sheaths and joints may also occur

The onset of the arthritic phase is often announced by a swelling of the proximal interphalangeal joints of the second and third fingers of both hands It is usually insidious but is acute in about 10 per cent of cases In the case of the former it is not uncommon for the disease to be marked by long periods of low and inter mittent fever The thyroid gland is also sometimes enlarged, and fibrositic pains may be complained of

Wasting of the small muscles of the hands is generally the next event and the fingers tend to fall into the position of ulnar flexion in which they may ultimately become fixed The affection then spreads centripetally towards the trunk involving in turn the wrists (which often become ankylosed) ankles elbows knees shoulders hips and jaw The bilateral and symmetrical way in which the joints tend to be affected is a striking feature of the disease In some cases the spine itself in due course becomes affected

Whenever a joint becomes involved it will be noticed that the muscles which control it particularly the extensors waste rapidly giving rise to the varying flexion deformities typical of the later stages These may be perpetuated by a fibrous anky losis of the affected joints and contraction of the joint capsule Bony ankylosis may follow this stage and when it does so it generally occurs in the wrists and the bones of the carpus in the first place

In certain cases enlargement of the lymphatic glands occurs and even the spleen may become palpable In those cases in which in addition leucopenia is present the condition is known as Felty s syndrome Sufferers with rheumatoid arthritis generally experience considerable pain which interferes with their sleep and this adds progressively to the severity of the condition

Symptoms often clear up if pregnancy or jaundice occurs during the course of the disease but in most cases they return with renewed vigour after parturition Periodical remissions are a well known occasional feature of the disease they may last for months or even years

Prognosis —Under a properly planned and supervised programme about 20 per cent of patients recover A further 50 per cent. show considerable improvement and an additional 20 per cent are improved to some extent leaving 5 to 10 per cent of cases which appear to be entirely resistant to treatment of all kinds With

modern methods of treatment, gross deformity should very seldom occur, even when ankylosis takes place It should be remembered however that in many cases treatment of some sort is required for months or even years, and that relapse may occur even after apparent cure If the disease is not checked, the end result is often complete and painful crippling This sometimes takes place within a very short period, particularly when the patient is young Cases which occur later in life tend on the whole to be less rapidly progressive in their course

Treatment—It is by a careful and intelligent selection and combination of methods suited to the individual patient that the most favourable results will be obtained A period of rest in bed is essential when the disease is progressing rapidly and there is much swelling of weight bearing and other joints

Diet—This should be rich in vitamins, especially the B complex and C, and extra calcium in the form of milk and cheese is advisable It should also be rich in calories, and there is no reason to restrict any particular type of food in this d se

When the sufferer is much underweight and does not return to normal by d tetic means alone, a small dose of insulin (5 to 10 units) may be administered 15 to 20 minutes before two meals in the day, the allowance of carbohydrates being adjusted accordingly

Physical therapy—In the acute phase these are of necessity reduced to sedative applications and gentle movements They may be supplemented by progressively graded ultra violet rays which stimulate to some extent the patient s powers of resistance Later massage, heat and supervised voluntary movements help to relax the muscle spasm, which is often in itself a cause of pain and tends to increase the ultimate deformity

Splints may be necessary at all stages, to prevent contracture and maintain movement in the affected joints

Drug therapy—Anæmia will respond to iron sometimes only when it is administered intravenously and on general principles the patient needs laxatives for constipation and analgesics for the relief of pain and sleeplessness If aspirin or phenacetin is not effective Dover s powder (gr 10 to 15) or codeine phosphate (gr ¼ to ½) may be tried A time honoured remedy is guaiacol carbonate which may be given with aspirin, thus Guaiacol carb gr 8 aspirin gr 4, in cachet form three times daily after food

Phenylbutazone (Butazolidin)—This drug has a powerful analgesic action on many patients with rheumatoid arthritis but in others it appears to be without effect It may be tried in severe cases before resorting to the use of cortisone The dosage should not exceed 200 mg three times a day because of the danger of toxic effects, which include nausea, vomiting stomatitis, œdema, agranulocytosis, hæmorrhages and skin eruptions

Gold is believed by many observers, to be the most valuable drug in the long term treatment of rheumatoid arthritis It appears to cause remissions in a high percentage of cases and is most effective when the onset of the disease is recent and the blood sedimentation rate is high This method of treatment is contraindicated in the presence of renal or hepatic damage diabetes mellitus eczema severe anæmia colitis, pregnancy, hæmophilia or purpura With regard to other cases the dangers of reaction complications and mortality should be taken into consideration There should be a complete blood count blood sedimentation test and an examination of the urine for albumin The main toxic effects are purpura boils, exfoliative dermatitis gastro enteritis and colitis nephritis aplastic anæmia and stomatitis There is however, a negligible mortality attendant upon this form of therapy The patient should not be exposed to strong sunshine or ultra violet light during the treatment for fear of pigmentation ✓

It is well not to administer gold near the period of the menses as skin eruptions are said to be more liable to occur then There are several preparations of gold salts

on the market It is wise always to employ those which are administered intra muscularly Whether they are suspended in an oily or in an aqueous solution appears to be immaterial The initial dose should be 0 01 g and subsequent doses may be 0 02 and 0 05 g This latter dose should not be exceeded nor should the injections generally be given more frequently than once weekly If no improvement follows the administration of 1 0 g of gold it should be discontinued but when the response is good relapse can usually be prevented by prolonging treatment for an indefinite period Injections of 0 05 g are given at 2 to 4 week intervals unless undesirable side effects occur The complete blood count blood sedimentation rate and urine examination for albumin should be repeated at regular intervals during the treatment If toxic effects are produced the injections should be discontinued immediately and on no account should the patient receive further treatment with gold Serious complications such as exfoliative dermatitis will respond to a short course of corticotrophin Dimercaprol (B A L) which is itself toxic need no longer be used for this purpose

Preparations of bismuth and copper have recently been introduced but it is the experience of British workers that they are not efficient substitutes for gold Prostigmine (physostigmine) has also been advocated as an antidote to muscular spasm which is a painful feature of certain cases of rheumatoid arthritis and a cause of increased joint deformities Current opinion in this country is however unfavourable

Vaccine therapy —This form of treatment is claimed sometimes to reduce the activity of the disease particularly when focal sepsis is an important factor in its ætiology The correct dose of the vaccine is probably the lowest which is found to provoke a favourable reaction and not the highest which can be tolerated

Protein shock may be given in the form of intravenous T A B vaccine injections This is a non specific procedure designed to raise the patient s temperature temporarily in the hope of benefiting him subsequently Such treatment should never be undertaken when the patient is in an active phase of the disease Once improvement has started however it may be justifiable to endeavour to speed its tempo by this means Three to five injections should be administered the dose varying according to the age and weight of the patient At least 24 hours of normal temperature should be allowed between the injections which should not in any case be given more frequently than twice weekly

Repeated blood transfusions apart from correcting the anæmia are sometimes of value in retarding the progress of the disease The value of blood from pregnant women for this purpose is being investigated Thyroid in small doses (gr ¼ to ½ twice daily) or iodine may be useful during the menopause

Focal sepsis —It is unwise to embark upon operative procedures while the patient is in a condition of debility or while the disease is running an acute febrile course with marked joint pain and swelling In such patients an endeavour should previously be made to build up the general health If after 4 to 8 weeks no improvement has occurred and the focus is still believed to be of importance cautious measures for its removal may be initiated The patient should in such cases be warned that it is unlikely that the removal of such a focus will cure the arthritis but that his general health and the powers of active resistance will be stimulated thereby The foci of infection which are of particular importance and should always be investigated are situated in the tonsils the nasal sinuses and the teeth but the colon appendix gall bladder cervix Fallopian tubes prostate and bladder should also be investigated If more than one focus of infection is found the one most apparently active should be treated first In cases in which the sinuses and the tonsils both require surgical attention it is important to allow a period of several weeks to elapse between any two operations

The steroid hormones —Cortisone and corticotrophin (A C T H) are not as valuable in the long term treatment of rheumatoid arthritis as first experience seemed to

suggest Suppression of the disease occurs in the majority of cases at the time of administration, but relapse almost invariably follows the withdrawal of treatment A lengthy course of treatment is justified in selected cases with rapidly worsening disease, and cortisone which can be given by mouth is the hormone of choice An initial dose of 100 mg daily, in three divided doses, is gradually reduced to 25 to 75 mg daily over a period of 2 weeks The equivalent amounts of long acting corticotrophin given intramuscularly once daily, are 30 to 60 mg initially, reduced to a maintenance dose of 20 mg Complete prolonged suppression of symptoms cannot always be achieved without the production of side effects These include rounding of the face, obesity, œdema, disorders of menstruation insomnia tachycardia and hypertension Hirsuties, acne, diabetes severe mental changes hæmorrhages and thromboses are less common

A short course of treatment can sometimes be given as an adjunct to physical measures aimed towards rehabilitation Definitive treatment with repeated short courses has proved disappointing Withdrawal symptoms in the form of weakness malaise loss of appetite and depression are common and in some patients they are more distressing than the disease When inflammation is limited to a few joints, the standard methods of treatment can be supplemented by the intra articular injection of small doses of hydrocortisone (compound F) The steroid hormones *should not be prescribed when disability is due to irreversible changes* and they are contra indicated by such conditions as peptic ulceration acute psychosis tuberculosis and severe acute infections They should be administered with caution when there is hypertension, diabetes or severe osteoporosis Patients on steroid hormone treatment must remain under regular observation

2 SPECIFIC INFECTIVE ARTHRITIS

GONOCOCCAL ARTHRITIS

From 1 to 5 per cent of those infected with gonorrhœa develop gonococcal arthritis The disease is also found in babies whose infection occurs at birth In view of the fact that infection due to this cause frequently ends in crippling and bony ankylosis of the affected joints it is important to make the diagnosis at the earliest possible stage If this is done the prognosis is good

The clinical appearance and course of gonococcal arthritis is similar to that of rheumatoid arthritis when the onset of this disease is acute A differential diagnosis may be made from the following points (1) A recent history of gonococcal infection or urethritis Unless specifically questioned patients often omit to mention this (2) The onset of joint symptoms within 3 weeks of such an infection (3) There is a predominance of 3 1 in males unlike true rheumatoid arthritis *As in the latter disease however the malady is often a polyarthritis from the onset* (4) The knees wrists ankles and frequently the plantar fascia are involved in a virulent attack A painful teno synovitis around the wrists and ankles is a common forerunner of arthritis (5) Conjunctivitis and irido cyclitis are not uncommonly associated with gonococcal arthritis

The complement fixation test of the blood is found to be positive in about 80 per cent of cases after the first month and gonococci may in many cases be grown by special methods from samples of the joint fluid affording an immediate confirmation of the diagnosis

Treatment —Although penicillin will invariably cure the primary infection it is less effective in the treatment of gonococcal arthritis and the most favourable results *have been obtained with artificial fever therapy* In the chronic stages it is important to guard against contractures of the affected joints

MENINGOCOCCAL ARTHRITIS

This is not uncommon in the second week of cerebrospinal fever and may be polyarticular or monarticular It closely resembles gonococcal arthritis except that it is generally less severe There is also a milder sporadic form—chronic meningococcal septicæmia—which occurs in the absence of meningitis and which is probably more common than is generally suspected passing as influenza or subacute rheumatism The diagnosis in these cases rests upon the presence of intermittent low fever a rash which may be purpuric and sometimes simulates erythema nodosum and a positive blood culture Leucopenia is usual in this syndrome The patients often seem surprisingly well and complain of little except joint pains Both these types respond well and rapidly to sulphonamide therapy

PNEUMOCOCCAL ARTHRITIS

A polyarthritis of the rheumatoid type is a rare sequel of pneumonia It affects children more commonly than adults An arthritis affecting one or more of the larger joints is somewhat commoner These conditions generally occur subsequent to the stage of pneumonic resolution

Pathology —The joint fluid is in most cases purulent and pneumococci can be found in it except in cases which have received chemotherapy

Prognosis —If the patient survives the pulmonary infection his resistance to the organism is good and joint function is in most cases preserved provided erosion of the cartilage has not taken place

Treatment —Joints affected in this way should be aspirated early and they should be immobilised in light plaster splints which should be removed daily to permit of gentle movement Specific treatment for the pneumonia must be given

ACUTE SUPPURATIVE ARTHRITIS

This is often polyarticular in its distribution and may be mistaken at first for acute rheumatic fever or rheumatoid arthritis It occurs more often in children than in adults

Ætiology —The condition may be a blood borne infection (metastatic) or may arise as an extension from neighbouring areas of osteomyelitis or other infection The former is the more common and may be secondary to a focus of infection in the middle ear throat sinuses or prostate It may also follow the acute specific fevers particularly scarlet fever and septic tonsillitis It has also been reported following meningitis septic endocarditis infected varicosities and burns pyelitis and furunculosis An arthritis following typhoid fever is not generally suppurative but may become so

The organisms which are chiefly responsible are the hæmolytic streptococcus the staphylococcus the pneumococcus the gonococcus and after typhoid *Salm typhi*

Symptoms —These include an acute onset of chills and sweats pyrexia local pain and tenderness in the joints with redness swelling and limitation of movement There is in most cases a high degree of polymorphonuclear leucocytosis

Course —The joint fluid rapidly becomes purulent and extensive damage to the joints occurs if treatment is not instituted rapidly Badly damaged joints generally ankylose ultimately The mortality amongst such cases used to be in the neighbourhood of 20 per cent

Treatment —Treatment with the antibiotic to which the organism is most sensitive should begin as soon as possible and in the case of penicillin or streptomycin it can also be given directly into the joint Pus should be removed by drainage or aspiration When the infection has been controlled impairment of function due to

muscle wasting will respond to exercises and other methods of rehabilitation but orthopædic treatment may be necessary when there are irreversible destructive changes in the joint

TUBERCULOUS ARTHRITIS

Tuberculous arthritis usually occurs in young patients and is an infection from a primary tuberculous focus elsewhere in the body The possibility of an arthritis in a young subject being tuberculous should always be borne in mind and a radiographic examination is of great value in differentiating this type from other varieties The subject is dealt with fully in surgical books to which the reader is referred

Tuberculosis may also be responsible for certain cases of idiopathic polyarthritis

DYSENTERIC ARTHRITIS

A polyarthritis of the rheumatoid type follows bacillary dysentery in about 3 per cent of cases at an interval varying from 3 weeks to several months after the cessation of acute symptoms It may also occur in the course of a chronic ulcerative colitis In some cases the process only affects one joint but in either event the process commences as an inflammation of the periarticular tissues and progressively invades the joint surfaces Suppuration is rare

Treatment should be directed to the dysenteric condition and should be palliative so far as the joints are concerned Severe arthritis due to ulcerative colitis is an indication for colectomy

REITER S DISEASE

This is an illness of undetermined ætiology which is often self limiting and which is characterised by polyarthritis in association with non venereal urethritis and conjunctivitis Attention was drawn to this syndrome during the campaigns in the Middle East where it was not uncommon amongst young soldiers It was originally held to be related to dysenteric polyarthritis but the consensus of opinion now tends towards a virus ætiology (see p 310)

UNDULANT FEVER OR BRUCELLOSIS

A mild polyarthritis due to chronic infection with the organism of this disease is probably more frequent than is usually believed and is commonly seen in Mediterranean countries It is generally associated with myalgia and sometimes with intermittent hydrarthrosis The onset may be acute or chronic and the clinical picture may closely resemble a subacute attack of rheumatoid arthritis The pain is often very acute

The general symptoms are indefinite and multiple and include malaise long continued low grade pyrexia which undulates loss of weight sweating and depression The blood may show a secondary anæmia and a leucopenia The agglutination tests are usually positive if the disease is of some weeks duration but a negative result is inconclusive The only fully satisfactory diagnosis is based on cultivation of the organism which is however very difficult

DENGUE

This disease gives rise to a very acute form of peri arthritis Intense pain and sometimes swelling occur in the tendons and muscles around the joints These

usually disappear when the fever subsides but in the stage of convalescence may recur and last for weeks or months The condition should be differentiated from rheumatic fever from which it differs in being epidemic and in not responding to salicylates

LEUKAEMIA

Acute leukæmia in children not infrequently presents with swelling redness and pain of one or more joints The disease may thus be confused with rheumatic fever or rheumatoid arthritis

DISSEMINATED LUPUS ERYTHEMATOSUS (see p 933)

3 OSTEO ARTHRITIS

Synonyms—Hypertrophic Arthritis Arthritis Deformans Morbus Coxæ Senilis (of hip)

Osteo arthritis is a degenerative condition which affects the articular cartilages and weight bearing surfaces in most cases of the larger joints

Ætiology—The known factors include trauma congenital joint deformity senility certain disorders of metabolism and nervous diseases *e g* Charcot s joint Prolonged toxæmia is occasionally important but there is no evidence that focal sepsis is con cerned in the ætiology of this type of arthritis There may be an hereditary factor particularly in certain cases of osteo arthritis of the hips

The malady tends to occur principally in men over middle life who have led a strenuous life in women it mainly affects the knees and is often secondary to the proliferative synovitis which is often a distressing feature of the menopause

Pathology—The changes which occur in the joint affect primarily the articular cartilage which in the early stages shows grooving and fibrillation starting at the points where the pressure of the opposing surfaces is greatest Later the cartilage may actually wear through at these points and the two bony surfaces come into contact When this happens the constant rubbing of bone on bone gradually polishes and eburnates these areas At the same time a gradually progressive enlargement of the articular surfaces occurs which culminates in the production of lipping and of bony outgrowths from the joint margins called osteophytes These excrescences may in well established cases be easily palpable at the joint margins and are the typical lesions of osteo arthritis No constant changes other than degenerative are found in the synovium

Symptoms—The onset of the disease is insidious The first symptom to be complained of is usually stiffness often accompanied by pain after exertion The site is generally one or more of the larger joints or it may be any joint which is sub jected to particular stresses as the result of the patient s occupation or recreation In the course of time considerable wasting of the muscles controlling the affected joints supervenes The joints therefore tend to become unstable and so liable to further trauma The coarse grating which can be elicited in joints affected with the disease is due to an accompanying teno synovitis and is no measure of the actual damage to the joints themselves When extrinsic joint changes have occurred the patient usually experiences considerable pain particularly on bearing weight The movements of the joint also become much limited on account of spasm of the sur rounding muscles which may in itself be a cause of pain There is generally not much effusion present Occasionally new bone formation may limit the movements of the joint although this is not very common Small rounded bony swellings on the terminal phalanges of the fingers and thumbs termed Heberden s nodes not

infrequently develop during the course of the disease. These may be the cause of considerable pain in their early stages, but, on the other hand they may be quite painless.

The examination of a hip joint affected with early osteo arthritis reveals some limitation and pain on rotation and often also of abduction of the joint some time before the movements of flexion and extension are appreciably interfered with. In addition, it may be found that such a patient when standing does not support his weight equally on both hips in order to avoid pain. Some wasting of the gluteus muscle on the affected side is also evident fairly early. In advanced cases actual shortening of the affected limb occurs either as the result of absorption of the femoral head or from its dislocation upwards. Pain complained of in the knee may in reality be referred from a diseased hip; in such cases if a full examination of the patient is omitted treatment may be directed to the wrong joint. 'Sciatica' is often found to be the result of osteo arthritis of the hip or of the lumbar spine, and is sometimes the initial symptom.

Osteo arthritic changes in the lumbar spine are frequently present without giving rise to symptoms and such changes are often discovered radiologically in the course of an examination for another purpose. The sacro iliac joints are in the same way frequently reported as being the seat of osteo arthritis. Many of these patients are symptom free, while others complain of low backache or sciatica.

The osteo arthritic joint does not ankylose but may become locked as the result of excessive osteophyte formation. In other cases it becomes unstable owing to continued use in the presence of insufficient muscular support due to muscular wasting; in these cases the joint surfaces may ultimately become very disorganised.

When a weight bearing joint is affected the patient suffers great pain on standing and a certain amount of absorption of articular bone may occur resulting in some shortening of the limb.

In some cases the articular cartilage may become fragmented or osteophytes may break off into the joint cavity. In both these circumstances they form loose bodies which give rise to all the symptoms usual in that condition in addition to those of the arthritis.

The general health is not affected unless as the result of enforced inactivity or of pain.

Diagnosis—Unless the observer be a slave to names it must be allowed that it is not always easy to call a case one of pure rheumatoid arthritis or osteo arthritis. But speaking generally, the distinction is a true one and it is important to make it whenever possible. Osteo arthritis is a degenerative condition affecting one or two joints, usually the larger ones. There is generally a history of trauma in the past, or of continued trauma of a minor nature such as some occupational or sporting stress or strain, or a postural defect, or in some cases a sudden increase of weight with resultant strain on the ankles, knees or hips such as may occur at the menopause. Apart from the menopausal group of cases the patient is more often a male and his general health is not directly affected by the disease. Again, the pain is generally relieved by rest.

Rheumatoid arthritis on the other hand is a general disease, the joint changes being a conspicuous part of it. These changes are inflammatory in nature, and trauma is not a marked feature. The onset is in the smaller joints, many of which are generally affected symmetrically and bilaterally. The patient is most often a woman and there are as suggested indications of general ill health and loss of weight which often precede the joint manifestations.

The *radiographic* appearance of a joint affected with osteo arthritis is usually typical. The bone density is unaffected but the joint space is narrowed to a degree which depends upon the amount of erosion occurring in the cartilage. Osteophytes are seen at the joint margins and there is frequently also a deposition of calcium in

the attached ends of certain tendons such as those of the patella and ligaments, *e g* the cruciates which result in an appearance of spiking This is sometimes found independently of the existence of osteo arthritis In osteo arthritis of the hip considerable deformity both of the head of the femur and of the acetabulum may be seen and in addition small degenerative cystic areas adjacent to the joint are not infrequently noticed The radiographic findings are often unrelated to the degree of pain in the particular case, this may be severe with very little radiographic deviation from the normal whereas the grossest radiographic changes are sometimes compatible with little pain

The blood sedimentation rate glucose tolerance test and streptococcal agglutination reaction are normal

Differential Diagnosis —Conditions which are liable to be confused with osteo-arthritis are Paget s disease osteochrondritis dissecans and occasionally neoplastic growths of the articular ends of bones

Prognosis —If not treated the course of osteo arthritis is progressive and generally ends in disablement Much however can be done in the early stage to prevent this by relieving the affected joint of all possible strain and by support and correct treatment The outlook is perhaps best in that form known as menopausal arthritis provided full and adequate measures are taken before the malady becomes firmly established

Treatment —As there is usually an absence of general symptoms there is no indication for general treatment other than seeing that the patients receive an adequate supply of vitamins and that definite periods of rest are secured If the patient is obese a diet low in fats and carbohydrates should be insisted upon if success from other measures is to be achieved The caloric value should not exceed 1600 calories and fluids should not be taken at the same time as food The patients should be reassured that they will not become extensively and hopelessly crippled as may occur in rheumatoid arthritis

It is the experience of most observers that little benefit is to be anticipated as the direct result of removing foci of infection If however these are found they should be dealt with on their merits If varicose veins are present as is often the case when the malady is situated in the knees treatment directed towards these may result in some improvement in the joints

The drugs chiefly valuable in this condition are those of the analgesic group such as aspirin phenacetin and codeine They should not be prescribed as a routine and should only be used when pain is severe Phenylbutazone is very effective in certain cases but must be prescribed with caution 200 to 400 mg daily may relieve the pain and this dose can be maintained over long periods with reasonable safety It can often be reduced to 100 mg daily with equal effect Gold salts are not indicated in this type of arthritis The intra articular injection of hydrocortisone 25 to 50 mg at frequent intervals gives considerable although temporary relief of symptoms in some cases

In cases which arise about the time of the menopause small doses of iodine and thyroid are often of value but should be combined with the other measures outlined particularly those for reduction in weight and muscular re education Central heating in the home is desirable

Physiotherapy of some sort is essential in the treatment of osteo arthritis Heat is required to stimulate the failing circulation locally and to relieve muscle spasm and consequently pain massage to maintain and stimulate the nutrition and drainage of the skin and underlying tissues and movement in order to maintain the mobility of the joint to prevent or repair muscle wasting and discourage the formation of adhesions When dealing with the extremities paraffin wax applied at a high temperature is also useful as a means of applying heat

Movement should if possible be active *i e* special exercises or if this is not

feasible at the outset, electrical stimulation by means of the surging faradic current, or hydrotherapy if available, may be substituted Movement of the affected joint should however, as far as possible be dissociated from weight bearing through the affected joint, in order to allow of repair in the cartilage Where the deep pool or the Guthrie Smith slings are available for this purpose they are helpful

The question of posture, or ' body mechanics ' is an important and neglected aspect in many cases of osteo arthritis For instance, pronated feet may cause strain and later, arthritis, in both knees and lumbar spine as may a pendulous abdomen Proper postural exercises should be taught, and the patient should continue with these until the correct posture is maintained reflexly

When after a period of rest the patient begins to put weight on to the affected joint again the latter should always be adequately supported For this purpose a crepe bandage, or Elastoplast is of great value In some cases special appliances, such as the Howard Marsh splint for the knees or a back support when the spine is affected, may be needed for a period in order to protect the joint For the feet proper arch supports may be necessary while in cases of severe arthritis of the hip or knee when weight bearing continues to give great pain some form of walking caliper, whereby the weight of the body is ' by-passed ' from the ischium down to the heel of the shoe by a light metal rod is indicated

In very advanced cases operative procedures may prove necessary Chief amongst these are synovectomy in those cases in which soft tissue proliferation is not responsive to other treatment When in the hip joint a small degree of painful movement is all that remains possible of achievement arthrodesis either by open operation or by means of the Smith Petersen pin is often the best method of treatment Arthroplasty in experienced hands is a successful operation but old age is a contraindication because of the considerable length of time necessary for rehabilitation Tavernier's operation for section of the obturator nerve if successful is pain relieving

4 HYPERTROPHIC PULMONARY OSTEO ARTHROPATHY (see p 1171)

5 ARTHRITIS DUE TO GOUT (see p 444)

6 SPONDYLITIS

Spondylitis is arthritis of the spine Most cases fall into one of three types (1) the ankylosing type—spondylitis ankylopoietica, (2) rheumatoid arthritis in which the spine is involved as part of the general disease and (3) osteo arthritis of the spine

1 ANKYLOSING TYPE OF SPONDYLITIS

Synonyms—Ankylosing Spondylitis Spondylitis Ankylopoietica Atrophic type of Spondylitis Spondylose Rhizomelique Von Bechterew's Disease Marie Strumpell Disease It is now realised that all these terms apply to the ankylosing type of spondylitis or sub varieties of this

Ætiology—The predisposing and exciting factors are probably the same as in rheumatoid arthritis In America where it is known as Rheumatoid Spondylitis it is believed to be a variant of that disease The age of onset is similar, occurring chiefly in the young but males are predominantly affected The disease is sometimes familial

Non specific urethritis is considered by some authorities to be a cause of ankylosing spondylitis

Pathology—The only true joints in the spinal column are those which permit of movement between the intervertebral articular facets and the costo vertebral joints

This type of arthritis commences as a synovitis of these joints followed by some *osteoporosis of the vertebral bodies and in the majority* of established cases radiological evidence of an infective process will also be found in the sacro iliac joints The ligaments surrounding the affected joints subsequently calcify and those portions of the spinal column become rigid When this process is complete the lateral borders of the intervertebral discs also calcify as do the anterior and lateral longitudinal ligaments the whole process resulting in a bamboo like appearance which is radiologically typical of the condition when fully developed

Symptoms—The early symptoms of ankylosing spondylitis are usually of a diffuse and insignificant nature and are therefore generally overlooked until they become localised in the spine which may be comparatively late in the disease The principal complaint is often of a diffuse fibrositis which chiefly affects the upper part of the body This syndrome if it persists should always arouse a suspicion of spondylitis in the case of a young male In others pain may be referred directly from the affected spinal segment and may simulate that of renal calculus pleurisy or even tabes Sometimes neuritis or numbness and loss of power in the limbs or severe spasm of the muscles of the back may be complained of All these symptoms are usually intensified on forced movement of the spine and in addition pain is often elicited by firmly tapping the spinous processes involved

There is also increasing stiffness in the back and ultimately this may become completely rigid (poker back) generally in a position of kyphosis and slight forward flexion of the spine In untreated cases this position becomes very exaggerated the chin sinks into the chest wall and the patient is unable to stand erect or move Those who are not bedridden move with a characteristic slow bent shuffling gait As the *costo vertebral joints ankylose so does the respiratory expansion of the chest diminish*

Complications—Those who die with this disease generally do so from respiratory infection the result of restricted chest expansion due to ankylosis of the costo vertebral joints The disease in itself does not usually shorten life

Diagnosis—All patients especially young and athletic males who complain of vague pains affecting the limbs and upper part of the body which do not respond *to treatment should be suspect The presence of detectable rigidity of the spine* is unusual at this stage If the blood sedimentation rate is high this increases the suspicion and should lead to the patient being radiographed The radiological appearances at this stage if present are loss of definition (woolliness) of the sacro iliac joints osteoporosis of the neighbouring bones and lumbar vertebral bodies Later the sacro iliac joints become obliterated and the intervertebral joints are hazy and later may be ankylosed The edges of the intervertebral disks and the spinal ligaments are calcified The vertebræ primarily affected are usually those of the lumbar and lower cervical portions of the spine Osteophytes are not found At this later stage the diagnosis becomes obvious as the whole spine is rigid The hip and shoulder joints are sometimes affected

Course and Prognosis—In cases in which the onset is acute ankylosis of the spine may occur within a few months The younger the patient the more likely is this to happen An associated swelling of other joints in the body develops at some period of the disease in about 25 per cent of all cases while the hips and shoulder joints are liable to be permanently involved in about the same proportion of cases Iritis occurs in a significant proportion

Treatment—It should be remembered that spondylitis of this type is a systemic disease and thus needs general treatment as well as more specialised attention to the spine Treatment is more successful if it can be started at an early stage of the disease The general treatment is similar to that advised for rheumatoid arthritis rest and a high caloric diet rich in vitamins Any definite foci of infection should be cautiously removed and anæmia counteracted Ultra violet light is a useful general tonic Gold salts do not appear to be useful in this condition Cortisone and

corticotrophin are of considerable value in suppressing the acute exacerbations The principles of treatment and dosage are the same as in rheumatoid arthritis (p 1152)

In the active stage rest in bed and mobilisation of the chest by means of breathing exercises are essential Fracture boards should be placed under the mattress to prevent sagging and the patient should be as flat as possible, the pillows being removed several times daily in order to hyperextend the spine Better still a plaster cast should be made of the back in which the patient can lie thereby maintaining the natural curves of the spine Breathing exercises undertaken in this position should aim at keeping the chest wall mobile by restricting abdominal breathing Physiotherapy is chiefly of value in the form of radiant heat or infra red rays to the back in order to relax spasm and relieve pain Gentle massage is useful for the same purpose and later active movements should be performed under supervision If there is already some deformity of the spine a plaster shell is essential and the patient should lie in this night and day to relax completely all spasm It should be altered frequently so as to take advantage of the gradual postural improvement, and when the patient first assumes the upright position he should be fitted with a light spinal brace to relieve the back from all strain Special mobilising exercises are indicated when the disease is less active

Radiotherapy to the sacro iliac joints and the spinal column is an important part of the treatment of these cases Its effect appears to be more than merely palliative

Even with the greatest care it is sometimes impossible to avoid ankylosis of the spine But if this does occur it is almost always possible to ensure that it does so in the optimum position and thus the patient will ultimately be able to lead a reasonably active life in an erect posture

2 RHEUMATOID ARTHRITIS WITH SECONDARY SPONDYLITIS (see p 1151)

3 OSTEO ARTHRITIC TYPE OF SPONDYLITIS

Synonyms —Osteo arthritis of Spine, Hypertrophic Spondylitis Degenerative Spondylitis Spondylosis

Some degree of osteo arthritis of the spine is present in the majority of people over 50 years of age, but it is unusual for these changes to cause symptoms Its incidence is rather higher in men than women and it seldom occurs before middle life It often follows trauma

Pathology —The changes are not inflammatory in nature and are identical with those of osteo arthritis met with elsewhere in the body Bony ankylosis does not occur in this type of arthritis but osteophyte formation is always seen together with narrowing and degeneration of the intervertebral spaces The areas most commonly involved are the cervical and lumbar regions and in the former protrusion of the intervertebral disks may result in spinal cord and nerve root compression

Symptoms —When symptoms are present they may include the following root pains of which sciatica is the most frequent example increasing stiffness of the back which however never becomes completely rigid Headache and pains in the neck shoulders and arms are common sometimes in conjunction with areas of paræsthesia or anæsthesia in the skin Pains are generally aggravated by movement of the spine, as the nerve roots are liable to pressure in or around their exit from the spinal foramina Cervical spondylosis may cause paraplegia due to ventral compression of the spinal cord a Brown Sequard syndrome due to lateral compression of the spinal cord and radicular symptoms when nerve roots are involved

Diagnosis —This should be confirmed radiologically The lesion typical of osteo arthritis is the osteophyte while marginal exostosis and shrinking of the vertebral margins with narrowing of the intervertebral spaces are also seen The sacro iliac joints are generally normal In all cases the possibility of malignant growths

or Paget s disease in the spine should be borne in mind as the symptomatology may be the same Myelography may be required to establish the diagnosis in doubtful ca es

Treatment —This i similar to that of osteo arthritis elsewhere in the body and includes the correction of body posture and flat feet The frequent application of heat in some form followed by rest and muscular relaxation is important Massage and faradism at a later stage helps the muscular support of the back Sometimes it is necessary to supplement the support of the back mechanically by a plaster cast or a brace Radiotherapy sometimes relieves intractable pain which proves resistant to analgesic drugs such as aspirin phenacetin codeine or phenylbutazone Conservative treatment of cervical spondylosis with neurological complications consists of bed rest physiotherapy and the immobilisation of the head and neck by means of a collar support Surgical treatment is confined to laminectomy because the offending osteophytic ridge is anterior to the cervical cord and is therefore inaccessible

7 STILL S DISEASE

This disease is believed by most observers to be the juvenile form of rheumatoid arthritis But although the articular changes are of an inflammatory nature their effects are more often confined to the periarticular tissues Again even in cases of long standing it is not unusual to find little or no radiological evidence of destruction at the actual joint surfaces

Ætiology —The sexes are affected in about equal proportion while the age incidence resembles that of rheumatic fever Thus the malady is seldom met with before the age of 3 years and the average age at onset is between 6 and 7 years The cause remains unknown although the factors held to be responsible for rheumatoid arthritis are usually invoked to account also for Still s disease These are focal infection metabolic or endocrine disorder or in some cases unsuspected and attenuated infection with the tubercle bacillus In the majority of cases it is very difficult to assign any one cause It is certain however that once the disease has commenced a cold damp environment exacerbates it considerably

Symptoms —If a careful enquiry of the history of the patient s illness be made it is often found that a considerable period of prodromal ill health preceded the onset of the joint symptoms

The onset of the joint condition is not infrequently rapid with pyrexia and pain and swelling of several joints This often leads to an initial diagnosis of rheumatic fever but it is soon found that sodium salicylate has no beneficial effect and that the joint swellings far from being transient increase in number and intensity When the onset is gradual there is little pyrexia but a slowly progressive degree of swelling and limitation in movement of the knees wrists elbows fingers and ankles—usually in that order Later the cervical spine and also the hips may become affected and the patient becomes completely crippled The foregoing joints are usually attacked symmetrically and their appearance is characteristic in that the periarticular swelling renders the joint fusiform in shape The skin over this swelling is rather stretched and often slightly bluish The muscles adjacent to the affected joints waste which further exaggerates the fusiform appearance In the case of the wrists ankles and elbows the bony contours are often completely obscured The affected joints are generally tender on pressure but usually are not painful except on movement This leads to further voluntary limitation of movement and so intensifies the muscle wasting already present

In many cases of this disease the joint swelling and muscular wasting are accompanied by a lymphatic reaction which shows as enlargement of the superficial lymphatic glands especially those around the elbows and in the axillæ In about half the cases

seen there is also enlargement of the spleen These changes were present in the cases originally described by Still in 1897 The enlarged glands are not tender and are generally discrete and ' rubbery Subcutaneous nodules are sometimes found in addition

There is generally a secondary anæmia, and quite often patches of light brown pigmentation on the skin When the disease is established the extremities are cold and clammy, and there is an increase in the temperature before other joints are affected In long standing cases normal growth is considerably interfered with

In the late stages the type of deformity seen in adult rheumatoid arthritis develops There is flexion of the fingers and ulnar deviation of the hands and also flexion of the knees and elbows

The radiographic picture is chiefly remarkable for the advanced degree of the osteoporosis which occurs There are often little or no actual joint changes, and osteophytes are never found

The end result, so far as the joints are concerned, is a fibrous ankylosis or a fibrosis of the joint capsule which is sufficiently complete to resist all attempts at movement of the joint

It is stated that at post mortem examination diffuse pericardial adhesions and adhesive mediastinitis are often discovered although unsuspected during life and evidence of valvular disease of the heart has occasionally been reported

Prognosis —Until recently there was considerable doubt as to what was the ultimate fate of these patients Some authorities held that they recovered while others explained the rarity of the affection in adult out patient departments by assuming that the patients either died or became rapidly bedridden after leaving the children s departments In one series the mortality in those under 5 years of age was about 25 per cent (due to intercurrent infections) complete recovery occurred in a small proportion while in the majority the disease remained apparently arrested often for several years at a time only to resume its ravages at increasing intervals until the patients were entirely crippled and bedridden

Treatment —When the presence of an infective focus is established this should be dealt with at an early stage of the disease In all cases the child s resistance should be built up by all available means A nourishing diet an open air life and a dry sunny climate are indicated In addition cod liver oil and malt syrup of iodide of iron, and courses of an arsenic containing tonic are important Salicylates have little or no beneficial effect Non specific protein therapy is often recommended but is too drastic and temporary a measure to employ except in the later stages Good results have occasionally been reported from small doses of gold salts administered intra muscularly in short courses But in some cases these salts provoke unfavourable reactions and so should be used very cautiously No case should receive a larger dose than 0 05 g and a total course of 0 5 g should rarely be exceeded The in jections should be given at fortnightly intervals, and the onset of toxic nephritis, stomatitis diarrhœa and dermatitis should be especially looked for The response to cortisone and corticotrophin is the same as in adult rheumatoid arthritis The initial response is generally excellent but as treatment may have to be protracted the likelihood of toxic effects is thereby increased

All swollen joints should be bandaged and lightly splinted or put into thin plaster of Paris casts to avoid the contraction deformities which otherwise inevitably occur The child should always sleep in these and soon becomes accustomed to them They should be removed daily however for a short period, during which the joint must be given active assisted movement to prevent fixation Dry heat from a radiant heat or infra red ray lamp is comfortable and renders the performance of these daily active movements easier These movements are also essential to remedy the muscular atrophy present Massage is generally unnecessary in these cases

In the very late stages, when the patient is bedridden owing to extensive contrac-

tion deformity minor surgical procedures such as tenotomy, are justifiable to remedy the deformity

PSEUDO ARTHRITIS (SYNOVITIS)

Effusion of fluid into the joints may be associated with various conditions and is often of a temporary or intermittent nature

Apart from the various forms of true arthritis already described the following may give rise to joint effusion

(i) *The specific fevers* especially scarlet fever meningococcal fever puerperal fever syphilis typhoid or paratyphoid fever yaws and malaria In the United States a form of pseudo arthritis associated with lymphogranuloma venereum is not un common

(ii) *Abnormal blood conditions* such as purpura simplex or purpura rheumatica (Schonlein s disease) scurvy and hæmophilia give rise to swelling of the joints due to an effusion of blood The knees are most frequently affected

(iii) *Growths affecting the bones* in near proximity to a joint

(iv) *Injection of animal sera* *i e* apart from serum sickness arising on the seventh to tenth day after the u e of foreign serum in treatment

(v) *Trauma* may cause synovitis or hæmarthrosis of the affected joint It should be noted that the strain imposed on certain joints due to faulty body posture occa sionally results in a chronic form of hydrarthrosis

(vi) *Intermittent hydrarthrosis* a periodic recurrence of joint effusion of unknown ætiology which persists for several days and usually affects the knees Attacks tend to recur at regular intervals they show no local evidence of inflammation and they are refractory to most forms of treatment This condition is probably the result of an allergic sensitisation and treatment should be directed along these lines It may represent an atypical form of onset of rheumatoid arthritis

(vii) *Palindromic rheumatism* —This is a form of recurrent painful swelling of the joints which shows intense inflammatory synovial reaction It has been exhaustively investigated by Hench but the cause remains unknown

NON-ARTICULAR RHEUMATISM FIBROSITIS

Non articular rheumatism and fibrositis are the terms employed to designate pain which is situated in the soft tissues of the limbs or trunk and of which the causation is obscure It is accompanied by muscle tenderness and spasm but there is no deterioration in the general health of the sufferer A feature of the classical type is that the pain can often be shown to originate in nodules which are acutely tender to pressure and from which the general pain is referred

In view of the obscurity which at present shrouds its true nature it can perhaps be best classified according to the part of the body which it affects *e g* fibrositis of the head and neck brachialgia intercostal fibrositis fibrositis of the back (lumbago) etc It may also be subdivided broadly according to the nature of the structures which appear principally to be affected *e g* *Panniculitis*—inflammation (or increased tension from some cause) of the deep subcutaneous fat *Peri arthritis*—inflammation of the structures surrounding joints (including bursæ) *Peri neuritis*—inflammation of the nerve sheath and fibrous tissue between the nerve fibres Considerable doubt has however been cast in recent years upon the occurrence of the latter as the result of rheumatism

Ætiology —Fibrositis can sometimes be attributed to focal sepsis particularly of the teeth tonsils nasal sinuses and prostate

A further group of cases would appear to be of metabolic origin *i e* allied to gout or to a special sensitivity to certain types of food It may sometimes be the outward manifestation of mental anxiety or tension and in America the term "psychogenic rheumatism" is much employed

Finally a certain proportion of cases of fibrositis can be traced to chronic strain often secondary to faulty posture A common example of this will be found in those cases in which the fascia lata is tender and painful in conjunction with a flattened plantar arch Such patients are usually cured when the distribution of the body weight is readjusted by raising the inner edges of the shoes Some cases of low back ache seem also to be attributable to the same cause

Morbid Anatomy—This was investigated originally by Stockman who believed that the results of injury to fibrous tissue, whether bacterial or traumatic had the effect of producing in the acute stage an exudate and inflammatory œdema As the condition becomes chronic there is said to be a production of dense connective tissue in nodules or strands, which differ from normal fibrous tissue in having more fibroblasts In 1944 Copeman and Ackerman produced evidence based upon biopsy, that certain cases of fibrositis are caused by a non inflammatory œdema of fat lobules which are invested with a non distensible fibrous fascia This increase in tension appears to be the cause of the pain In later stages the lobule may actually herniate through a weak spot in its fascial covering producing a tense palpable nodule

F A Elliott has suggested that in some myalgias and also in some cases of "fibrositis" local areas of tenderness or 'nodules' may be the result of muscle spasm centrally induced through irritated nerve roots

Symptoms—The pain complained of in fibrositis is not always at the real seat of the lesion but may be referred from other areas and therefore careful location of the actual seat of the inflammation is essential Again, the symptoms vary according to the area of the body affected As examples the predominant effect of involvement of the muscles of the neck is often headache, of those of the limbs numbness and tingling and of the fibrous tissue surrounding joints stiffness and pain on moving these often wrongly attributed to true arthritis

Panniculitis is met with most typically in the early stages of ' menopausal arthritis in which tender pads of thickened adipose tissue are found over the internal aspects of the knees the back of the neck the extensor surfaces of the arms the outer aspects of the thighs and elsewhere It occurs most frequently in stout people, and Dercum s disease or adiposis dolorosa is an extreme degree of this process In some cases this syndrome appears to be associated with moderate hypothyroidism Nodules which are not tender, are often felt in these and other patients

Lumbago is perhaps the most common manifestation of fibrositis Its onset may often be very acute It should be distinguished from arthritis neoplasm or caries of the spine sacro iliac disease, perinephric abscess and renal disease all of which may simulate it *Sciatica* is in a majority of cases probably due to a central lesion of one of the lumbar nerves often a prolapsed intervertebral disk neoplasm or inflammatory lesion (see p 1581) It must not be forgotten however that an appreciable number of cases remain in which the lesion is due to fibrositis *Pleurodynia* is a rheumatic inflammation of the intercostal muscles which gives rise to severe pain when the affected muscles are brought into action as on coughing or deep breathing Usually local tenderness can be elicited on palpation but careful examination is needed to exclude such sources of pain as pleurisy, cardiac disease intercostal neuralgia or prolapse of a thoracic intervertebral disk These muscles are also affected in epidemic myalgia (Bornholm disease) The extensor region of the thighs when they are the seat of rheumatic lesions give the clinical appearance of sciatica and this possibility should always be considered before making a diagnosis

Brachial neuritis—Brachial neuritis in its strict sense is usually an ill founded diagnosis though acute infective radiculitis is a genuine entity The commonest

cause of severe bilateral brachial neuritis is a cervical intervertebral disk lesion unilateral brachial neuritis is frequently due to supraspinatus tendinitis which is often the cause of inflammation of the subacromial bursa through which this tendon passes Another group of causes of brachial neuralgia are the cervico brachial syndromes which include the compression of vessels or nerves at the thoracic outlet by a cervical rib or an abnormally placed clavicle or a spastic scalene muscle (acro paræsthesia) These are all dependent upon a mechanical factor of some sort (see pp 1577 1579) Tennis elbow is the term applied to the painful fibrositis affecting the origin of the extensor tendons of the forearm from the external condyle of the humerus

Bursitis may occur in any of the large bursæ The most commonly affected is the subacromial bursa referred to above The chief clinical manifestations of deltoid bursitis are great pain on actively abducting the affected arm to an angle of 90 with the body Above this point abduction can generally be completed without pain the pain returning however at the same point when the arm is again lowered Passive movement through this range is not painful Pain of this type encourages the sufferer to immobilise the affected arm and this allows the inflammation to spread to the joint capsule which contracts and ultimately limits or even entirely prevents movement in the joint This *frozen shoulder syndrome is not* an infrequent late complication of cardiac infarction The patient is often unaware of the full degree of limitation of the movement which has occurred in such cases as a considerable degree of movement is possible by virtue of the mobility of the scapula This condition is the severest type of peri arthritis and the apparent ankylosis of the joint must be differentiated from a true arthritis by means of radiography as peri arthritis of this type may be cured by the employment of diathermy with active assisted movements and remedial exercises or if the diagnosis is clear and these means fail by manipulation under anæsthesia The bursæ next most commonly affected are those over the olecranon process around the knee joint over the ischium and over the great trochanter Inflammation of any of these should be differentiated from a true arthritis of the neighbouring joint Another form of peri arthritis depends on inflammation of the tendon sheaths of muscles surrounding joints This may occur as part of a chronic rheumatic process unassociated with trauma or gout Its association with gonorrhœal and dysenteric infections has been mentioned The flexor tendons of the wrists and knees are the most commonly attacked Pain swelling or crepitus results and sometimes synovial effusion Occasionally the extensor tendon of the thumb alone becomes painful and thickened resulting in a loss of abduction and great tenderness and thickening This is referred to as stenosing tendovaginitis (De Quervain s disease) and is brilliantly amenable to operative treatment

The palmar fascia is sometimes the site of a chronic fibrositic process and the resulting thickening and contracture is known as *Dupuytren s contracture* This is seldom painful but can give rise to considerable disablement of a somewhat intractable nature The condition which is much commoner in males than in females is often found to be familial A somewhat similar condition which however does not cause so much contracture is known as painful heel In some cases a small spur of bone is found radiographically at the insertion of the plantar fascia into the os calcis though spurs may also be found in subjects who are free from the condition But in the majority of cases no cause for the pain can be found

The subjects of fibrositis are usually found to have some degree of defective skin circulation as evidenced by abnormal sensitivity to cold weather or to local draughts spontaneous bruising or the fact that they perspire in the hottest weather only with difficulty Attacks of fibrositis occur in many people without apparent detriment to their general health

The group of cases which appear to be allied to gout or to a special sensitivity to certain types of food may be suspected by the excellent general health even during

attacks the periodic or seasonal nature of the attacks a history of familial gout or of being "unable to digest certain foods or drinks and finally by the fact that the fibrositis tends to affect the lower limbs and other lower parts of the body Such patients in addition often exhibit the symptom complex described by the French as hépatisme' This is shown principally by morning headache furred tongue and a tendency to incomplete bowel emptying with light coloured and offensive stools, often too, there is slight tenderness on palpation of the liver

Prognosis—Provided sufficient care be taken and the value of external as well as internal remedies is remembered, the outlook is good An exception, however is in the case of old patients for the senile form of fibrositis is sometimes intractable to all the usual remedies

Treatment—When symptoms do not call for urgent treatment, the first indication is to investigate the ætiology In the majority of cases in which the malady is believed to be allied to gout or due to a special sensitivity to certain types of food appropriate treatment should be adopted

At the outset, a mercurial purgative such as calomel (gr ¼ to 2) followed next morning by a saline should be prescribed In the acute stage rest in bed is desirable The internal administration of analgesic drugs is indicated Aspirin and calcium acetylsalicylate (gr 5 to 15) are in the majority of cases the most efficient for this purpose If necessary potassium iodide (gr 2 to 5) may be added as may phenacetin (gr 5 to 10) or caffeine (gr 5) at 4 hourly intervals A useful addition to aspirin and phenacetin is codeine phosphate (gr ⅛) or Dover s powder (gr 5 to 15) Phenyl butazone (200 to 600 mg daily) is sometimes effective An ointment designed to act either as a rubefacient or as a counter-irritant should also be prescribed In acute cases a hot linseed or kaolin poultice will often give considerable relief if applied every few hours as may a hot cloth wrung out of a solution of ordinary mustard in water Massage is undesirable in the acute stage In certain cases benefit will result from a short course of colonic lavage twice a week for 2 to 3 weeks

When it is desired to immobilise the muscles of the back during the acute stage of lumbago the most effective method is by means of a perforated belladonna plaster which should be made to cros the mid line behind and come round to the front *Ordinary wide strapping is a good substitute When the condition is less acute* and the patient is able to get up the application of both heat and massage to the affected regions is indicated The former may be applied in a dry or a moist form the one often succeeding when the other has failed Dry heat may be given by means of a portable lamp, an electric heating pad exposure to a gas fire (which gives out infra red rays) the application of a hot iron through brown paper applied to the skin a hot water bottle or a bag of salt or sand which has been heated thoroughly in the oven When the condition is deep seated diathermy is the best form in which to apply heat

Moist heat may be applied in the form of bread or linseed poultices kaolin poultice (Antiphlogistine) mud packs or applications of hot paraffin wax of a special melting point (which is sold for this purpose) or if the patient is in a condition to have it a Turkish bath Perhaps the simplest method of applying moist heat is in an ordinary bath to which 4 lb of Epsom salts (or common salt) have been added It should be taken as hot as possible and contrary to the general belief the patient should not soak in it but should get out after only 10 minutes immersion and be briskly rubbed down after which some analgesic ointment should be rubbed rapidly into the affected areas and he should be wrapped in a blanket and put to bed for several hours After this deep massage should be ordered for the affected areas although this may be painful at first

Hydrotherapy and counter irritation—When the patient is near a spa or an institution equipped for hydrotherapy spray douche massage followed by contrast douching (alternate hot and cold water directed on to the painful areas under pressure

from a hose pipe) is probably the best follow up treatment it stimulates the skin and muscles to resume their normal functions

In certain cases particularly when the complaint is that of lumbago counter irritation by means of a cautery may be of great value A small blister should result from each application and the whole area may then be covered over with a gauze dressing Another method is to produce blisters by means of blistering fluid or cantharidin plasters but these are not of such value as the actual cautery Dry cupping is a somewhat obsolete method of treatment but is occasionally effective as is full exposure to a Kromayer mercury vapour lamp

In the chronic stage massage is essential if an attack is to be terminated in the minimum time and also if recurrence is to be avoided To be effective the indurated areas (nodules) should be carefully sought for in the muscles and at these points the massage should be deep It will be found that following deep kneading with the finger tips or thumbs after an initial period during which the nodules may be increasingly painful they will gradually become insensible to palpation and ultimately disappear This process will be considerably facilitated if it be preceded on each occasion by 20 to 30 minutes application of heat in one of the forms mentioned above In certain cases a nodule will prove to be too painful for deep massage treatment which will then induce protective spasm in the surrounding muscles and so render further kneading impossible In such cases a dose of aspirin or some other analgesic may usefully be administered before beginning the treatment When one or more discrete trigger points or nodules can be localised and when the pain is referred from these sites the effect of injecting a few millilitres of a local anæsthetic such as procaine hydrochloride (½ per cent in saline) or A B A compound with saline under pressure is sometimes dramatic When there is diffused pain and tenderness this method of treatment is not of much use and unless the injection is made with great accuracy into the nodule the trouble may even be exacerbated There is no doubt however that to achieve a quick result even if it does not prove to be permanent this is the method of choice

Diet and after care —If obesity be present this should be treated (see p 450) In cases in which a gouty origin is suspected this should be corrected (see p 448)

After an attack of fibrositis it is important that the patient should be taught to contract the affected muscles daily by means of appropriate exercises He should also make a point of obtaining some regular exercise in the open air, even at the cost of rising somewhat earlier in order to walk part of the way to the office The obese subject must not be allowed to regain his lost weight once the attack recedes and occupations or hobbies known to precipitate the attacks must be avoided

MYOSITIS OR INFLAMMATION OF THE VOLUNTARY MUSCLES

Three forms occur—(1) the suppurative type (2) the non suppurative type and (3) myositis ossificans progressiva

1 Suppurative Myositis —In this condition there is a primary inflammation of the affected muscles associated with the local signs of inflammation and the general symptoms of a septic infection Abscesses form in the affected muscles which may require incision and in the pus obtained pyogenic organisms such as staphylococci or less commonly streptococci are usually found

2 Non Suppurative Myositis —It must be remembered that the voluntary muscles are affected in the course of several diseases Thus degeneration of the striped muscle known as Zenker s degeneration may occur in any acute infection of long duration it was first observed in typhoid fever In scurvy intra muscular

hæmorrhages are common and these may be followed by a chronic inflammation which usually resolves but in a few such cases suppuration occurs Trichiniasis is accompanied by myositis set up by the encapsulated larvæ of the *Trichinella spiralis* deposited in the voluntary muscles

Dermatomyositis see p 936

3 Myositis Ossificans Progressiva —This is a progressive inflammatory affection of the locomotor system of unknown origin characterised by the deposition of bony substance in the fasciæ muscles aponeuroses tendons, ligaments and bones with resulting ankylosis of the affected articulations The disease is rare It usually commences in early life and is commoner in males Three stages occur in the muscle changes In the first stage swelling and infiltration of the affected muscle *with embryonic connective tissue occurs In the second stage the embryonic* connective tissue becomes organised and forms ordinary connective tissue, which retracts to a hard fibrous mass In the third stage calcification of the fibrous mass occurs and this becomes replaced by bone

The muscles of the back and neck are usually the first to be involved The vertebral ligaments become ossified and the irregular bony swelling produced causes deformity and fixation of the spine The upper and lower limb are later involved the muscles contracting and causing fixation of the joints Finally, the muscles of mastication are affected and this prevents movement of the lower jaw The patient becomes helpless and bedridden, and usually dies from some intercurrent infection, such as pneumonia or pyæmia resulting from bed sores The disease is always progressive but is usually of long duration, and there may be a cessation in its progress for several years No specific treatment is known

W S C Copeman

SECTION XVI

DISEASES OF THE SKELETON

DISEASES of the skeleton will be considered under three headings according to whether bone cartilage or bone marrow is primarily affected

DISEASES OF BONE

HYPERTROPHIC OSTEO-ARTHROPATHY

Synonyms —Hypertrophic Pulmonary Osteo arthropathy Secondary Hyper trophic Osteo arthropathy Marie s Disease Bamberger Marie s Disease Acropachy Simple clubbing is sometimes referred to as Hippocratic Fingers

Definition —A symmetrical enlargement of the bones of the hands and feet and of the distal ends of the long bones accompanied by clubbing of the fingers and toes and sometimes by joint swellings occurring in association with certain chronic diseases especially of the chest and abdomen Clearly simple clubbing of the fingers which is a common phenomenon exists in countless patients without advancing further to produce hypertrophic osteo arthropathy which is rare

Ætiology —The disease is eight times more common in males than females It may occur at all ages including childhood The most striking examples are seen from 30 to 50 The primary diseases in the course of which hypertrophic osteo arthropathy may develop are

1 Diseases of the lungs such as abscess of the lung empyema bronchiectasis carcinoma of the lung and mediastinum or endothelioma of the pleura The condition is rarely seen in cases of pulmonary tuberculo is or non tuberculous fibroid lung

2 Congenital heart disease and infective endocarditis Here there is clubbing of the fingers but the bones are not affected

3 Diseases such as dysentery idiopathic steatorrhœa subphrenic abscess pyelo nephritis polycythæmia rubra vera and hypertrophic cirrhosis of the liver

4 In 10 to 15 per cent of cases the most minute search may fail to reveal a primary cause for the disease Such cases may be familial

5 Pressure on the brachial plexus by a subclavian aneurysm has been known to cause the disease which is then unilateral and confined to the upper limb concerned

Pathology —The bones most frequently affected are the metacarpal bones and the first two rows of phalanges There are no bony changes in the terminal phalanges the soft tissues and nails alone being involved The radius and ulna may be affected and more rarely the lower ends of the humerus and femur the scapula patella iliac crests nose and malar eminences Radiographic examination shows a thin layer of newly formed bone beneath the periosteum which is raised unevenly so that its outline appears serrated and the deposits beneath it are unevenly calcified giving a lace work effect

Symptoms —The onset is usually gradual with little pain though stiffness and clumsiness of movements occur Sometimes marked clubbing of the fingers develops in a few weeks but usually several months or more elapse before the condition is characteristic There is a remarkable symmetry in the pathological changes The ends of the fingers and toes may be cyanosed The nails are large broad and curved

both longitudinally and transversely—the so called parrot beak or drumstick They show longitudinal striation and are brittle and easily split The root of the nail is raised above its bed and if pressure is applied at the root a distinct space between them can be made out The hands and feet become greatly enlarged owing to the bony changes and thickening of the soft parts The forearms and legs are thickened The pelvis sternum ribs and clavicles may be thickened and the vertebræ may show changes resulting in kyphosis Swelling of the joints occurs in about a third of all the reported cases and in practically every one of those in which the process is of long standing The joints involved are those in the neighbourhood of the bones affected, particularly the knees ankles and wrists The lesions are not confined to the synovial membranes and periarticular tissues but may progress to erosion of the articular surfaces Acute painful swelling of the joints occurs especially in cases of endothelioma of the pleura

Diagnosis—The disease is recognised by the presence of the characteristic changes in the extremities and by the presence of signs of one of the primary diseases already mentioned

Acromegaly is to be distinguished by the spade like hand the spatulate fingers enlarged knuckles and the characteristic facial appearance The kyphosis is more often cervico dorsal whereas in hypertrophic pulmonary osteo arthropathy it is more often dorso lumbar

Osteitis deformans shows irregular enlargement of the bones but there is a good deal of bowing the hands are normal and the radiographic appearances are pathognomonic

Rheumatoid arthritis is distinguished by the involvement of the joints of the fingers the absence of clubbing and the changes shown by radiographic examination

Prognosis—Where successful treatment of the primary disease is possible simple clubbing of the fingers may disappear entirely This commonly occurs in empyema and subphrenic abscess In a similar way regressions can occur both in the soft tissues and in the periosteal changes in hypertrophic osteo arthropathy In some cases however cure or arrest of the primary lesion may have no effect on the osteo arthropathy Many cases progress unchecked until they show extreme changes in the skin nails soft tissues bones and joints A considerable degree of ankylosis of the knees sometimes occurs

Treatment—This should be directed towards the cure or improvement of the primary disease Other treatment is symptomatic Care should be taken to avoid ankylosis of the knees at an awkward angle

OSTEITIS DEFORMANS

Synonym—Paget s Disease of Bone

Definition—A chronic and somewhat rare disorder causing enlargement and deformity of many bones It is not a generalised disease of the skeleton The bones are affected in the following order of frequency pelvis spine femur tibia skull fibula clavicle, humerus radius and rib In a few cases the disease is confined to one bone or to part of one bone tibia femur clavicle a vertebra the ilium or half the pelvis

Ætiology—This is unknown The disease is sometimes familial It rarely begins before the age of 40 and the commonest age of onset is 55 The sexes are affected in the proportion of 3 men to 2 women Osteitis deformans is not inflammatory in origin It seems likely that it is a disorder of mineral metabolism Syphilis is not an ætiological factor No alteration in the parathyroid glands nor in any other endocrine gland has been demonstrated Both histological and chemical investigations

have proved beyond doubt that generalised osteitis fibrosa (hyperparathyroidism) is unrelated to osteitis deformans

Pathology —There is a great alteration in the architecture of the bones affected They become enlarged irregularly thickened and sometimes bowed The skull is very thick the sutures and foramina being narrowed in consequence The cortex of the long bones ceases to be pure ivory bone but looks coarse and spongy with red streaks and dots Histologically there is continuous excessive resorption of bone associated with an increased new bone formation that more than compensates for the bone lost The excessive erosion disturbs the skeletal architecture the compact bone being replaced by irregular angular trabeculæ which also form the cancellous bone There is still an attempt at structural adaptation to stresses but this is very imperfectly achieved because the material is not used to the best mechanical advantage

Biochemistry —The serum calcium and plasma phosphorus are normal The plasma phosphatase is constantly high as in many other diseases of bone In more than 80 per cent of cases the calcium output in the urine is increased and sometimes reaches four or five times the normal figure There seems to be a complete absence of correlation between the length of history the density of bone shadows in radio graphs and the calcium output A case showing increased density of bone trabeculæ throughout pelvis lumbar spine and femora is just as likely to reveal a high output of calcium in the urine as a low output

Symptoms —The disease may remain symptomless for 10 years or more It is very slow in progress and rarely influences the general health giving rise in most cases to few symptoms other than those which are due to changes in the shape of the bones In 80 per cent of cases there is pain and the patient usually recognises its origin in the bones It varies widely in severity from a dull ache to a severe shooting or stabbing like a knife The back and lower limbs are the parts usually affected but headache is fairly common When the skull is involved the patient may have to take a larger size in hats The enlargement in the circumference of the head leads to the forehead being prominent and the face small in proportion In the later stages the head is held forward and the back is so bent that the arms appear too long and an ape like attitude results There may be considerable reduction in total height The lower limbs especially are bowed the knees being widely separated and held slightly flexed The bones are enlarged and bowing usually takes place in such a manner as to accentuate the normal curve of the bone The enlargement is particu larly noticeable in the case of the tibia The changes in the vertebræ may cause encroachment on the spinal canal resulting in compression paraplegia Bony com pression of the optic nerve may lead to optic atrophy and of the oculo motor nerves to diplopia Otosclerotic deafness is common in advanced cases Spontaneous fracture is rare but when it takes place there is no delay in union Osteogenic sarcoma may occur but is much less common than Paget thought and is not seen until the changes in the bones have been present for 10 years or more Osteo arthritis of the hip knee ankle or spine is an occasional complication Arterial degeneration some times with hypertension is found in most cases over the age of 50 It is possible that the excess of phosphoric esterase in the blood accelerates and intensifies the deposition of calcium salts in degenerate vessels Retinal arteriosclerosis is a frequent finding and it may be associated both with retinal hæmorrhages and extensive choroidal changes

Radiographic appearances —The altered bone appears in radiographs in two forms which may be called the spongy and the amorphous the former being the more com mon The two types are often found in the same patient The spongy form consists of coarse irregular striæ arranged either as parallel trabeculæ or running in the direc tion of normal lamellæ of cancellous bone The amorphous form is a generalised deposit producing an opaque finely granular appearance The diameter of the bone is increased sometimes to a marked degree and in the medullary cavity the trabeculæ

are accentuated and too widely separated giving a streaky appearance The corticalis is partly or entirely replaced by bone similar to that seen in the medullary cavity, and in an extreme case the *impression is that the whole bone consists of cancellous* tissue highly magnified Irregular cyst like areas are sometimes observed Widening and bowing of bones are important points in the radiological diagnosis The vault of the skull is thickened, and the differentiation between the inner and outer tables is lost Small islands of dense bone are evident alongside pale cyst like areas A large clean cut area *osteoporosis circumscripta* may sometimes be noted In those cases in which part of one bone is affected there is a definite line of demarcation where the abnormal ends and the normal begins Thus there may be definite changes in the upper two thirds of the tibia while the lower third is normal The average rate of progress of such a lesion is about 1 cm in 2 years Radiographs reveal the shadows of arterial calcification in more than 40 per cent of cases Such calcified arteries are best seen in the lower limbs There is no evidence of a higher incidence of renal or vesical calculus in osteitis deformans than in the normal

Diagnosis —When advanced the condition is unmistakable In the early stages muscular rheumatism or osteo arthritis may be wrongly diagnosed Pulmonary osteo arthropathy is distinguished by the clubbed fingers In radiographs the amorphous type of osteitis deformans is sometimes mistaken for secondary carcinomatosis of the osteoplastic type The difference is distinct and important namely that in carcinomatosis the bones are neither enlarged nor bowed Syphilis of bones is now very rare but when only one or two bones are involved in a supposed case of Paget s disease the Wassermann reaction should be performed

Prognosis —Because the disease is uncommon there is a tendency to regard its effects as dreadful To announce the diagnosis as though it were a profound mystery may alarm both patient and relatives unnecessarily Paget s disease is slowly progressive but does not usually shorten life Thus one patient though much deformed continued to drive a crane in a dockyard 15 years after the onset of the disease Another was quite happy to have somebody hold him on a rock while he fished a stream long after he was unable to walk unaided Death usually results from the effects of arteriosclerosis or intercurrent infection and only rarely from compression paraplegia or sarcoma of bone

Treatment —No known treatment alters the course of osteitis deformans in the slightest degree *Since the bones at one stage are sufficiently decalcified to bend* methods have been used which aim at increasing the calcium intake The patient is given a high calcium diet that is a diet containing 3 pints of milk or milk products daily together with butter cheese and eggs If milk is not tolerated in these quantities calcium caseinate or calcium lactate (10 g a day) may be prescribed Vitamin D may be conveniently given in the form of tab calciferol (3000 units) one or two daily The claim that prolonged exposure to general ultra violet irradiation has resulted in increased density of the shadows of bones *in radiographs has not* been confirmed Such treatment can be carried out starting with short exposures to the mercury vapour or carbon arc lamp Paget treated his patients with potassium iodide but was not enthusiastic over the results When there is pain in the bones Lugol s solution (of iodine in potassium iodide) may be given in milk beginning with a dose of 3 minims three times a day and increasing to ten times this amount *If* iodine fails to relieve the pain aspirin or tabs codeine co *B P should be tried Exploration* of the neck for a parathyroid tumour is never justified Osteotomy is rarely necessary but it is interesting that when portions of bone have been removed for histological section relief of pain has sometimes occurred Occasionally and especially in those cases with secondary osteo arthritis of the hip joint or knee joint an ambulatory splint supporting the weight of the body on the tuber ischii is of value *A cork sole is often necessary* and when kyphosis causes pain a spinal jacket is useful

LEONTIASIS OSSEA

Synonyms —General Hyperostosis of the Skull Cranio sclerosis Megalo cephaly, Fibromatosis Osteoplastica Osseum

Definition —The term leontiasis ossea is now used in two senses specifically *for* a progressive sclerosing hyperostosis of the skull and *symptomatically* when osteitis deformans and the various types of osteitis fibrosa happen to involve the bones of the calvaria and face

Ætiology —This is unknown The fact that the disea e commonly arises in the region of the nasal sinuses has led to an erroneous view that it is infective in origin

Pathology —When Virchow suggested the use of the term leontiasis ossea in cases of hyperostosis of the skull he had in mind fibroma molluscum in which masses of new connective tissue develop in the skin He believed that the overgrowth of bone in hyperostosis corresponded exactly to elephantiasis of the soft parts and he decided to call these cases leontiasis ossea not becau e the bone disease produced a leonine appearance but because he considered it to be analogous to the disease of the soft parts which did The disease is very rare It occurs in either sex arising usually in early adult life In most instances it begins in the nasal fossæ and sinuses though in some cases the origin is near the orbit or in the base of the skull Dense ivory bone appears and spreads slowly under the periosteum being held up sometimes in the region of the suture lines but ultimately breaking through and spreading in many directions across the skull The serum calcium and plasma phosphorus are normal

Symptoms —The early clinical features include nasal obstruction blocking of the lacrimal ducts and alteration in the shape of the face and jaws Ultimately large masses of bone increasing in various directions give rise to terrible disfigurement The cavities of the mouth nose and orbit may be greatly lessened The eyeballs may protrude even beyond the lids and blindness may occur from optic atrophy There may be loss of the sense of smell and interference with the mobility of the lower jaw Except in the later stages pain is unusual

Diagnosis —Paget s disease usually begins at 55 and the pelvis spine and lower limbs are nearly always affected Generalised osteitis fibrosa leads to decalcification of the whole skeleton with a high blood calcium and low blood phosphorus Focal osteitis fibrosa often shows multiple lesions scattered throughout the skeleton

Treatment —No treatment has any permanent effect though it may be possible to remove some of the more disfiguring masses of bone

HYPERPARATHYROIDISM (GENERALISED OSTEITIS FIBROSA CYSTICA (see p 501)

FOCAL OSTEITIS FIBROSA

Synonyms —Osteitis Fibrosa Circumscripta (Schmidt) Local Fibrocystic Disease Benign Giant celled Tumour Osteoclastoma Osteogenetic Myeloma Myeloid Sarcoma

Definition —A focal or multifocal disease of bone unassociated with constitutional symptoms or with any known endocrine disturbance

Ætiology —This is unknown The disease occurs chiefly in adolescence and is much more common than is generalised osteitis fibrosa (hyperparathyroidism)

Pathology —The lesions are benign firm grey or brown tumours Histologically

they show osteogenetic fibrous tissue and giant cells which, of course are osteoclasts This explains the numerous synonyms which are used The tumours sometimes expand the corticalis and may give rise to cysts lined by osteoclasts Even when the lesions are multiple the rest of the skeleton consists of normal bone The figures for serum calcium and plasma phosphorus are invariably normal, a finding in striking contrast to that of the generalised disease The calcium balance is usually normal and, taken in conjunction with the normal blood chemistry, this finding is strong evidence against hyperparathyroidism

Symptoms —The malady affects one or more bones, is usually not disabling is of slow progress and shows a tendency to become arrested Pain is unusual and the disease is often symptomless until spontaneous fracture occurs Severe cases of the multifocal type may show considerable deformity, especially of the pelvis femora and skull

Radiographic appearances —In radiographs the principal changes are found in the ends of the long bones Usually more than one third of the shaft is affected by a fusiform enlargement composed of a pale cyst like area divided by a few coarse trabecular strands The cortex is thin and may be expanded The periosteum and adjacent bone are normal Radiographs taken with controls show that the whole skeleton apart from the lesions is normally calcified The floor of the skull and the lower jaw may be affected

Diagnosis —The normal blood chemistry serves to distinguish the focal from the generalised disease In adult cases it is sometimes difficult to differentiate between focal osteitis fibrosa and osteitis deformans and it may then be necessary to follow the progress of the condition over a period of time before a definite conclusion is reached

Treatment —Fractures are treated in the usual way If spontaneous fracture occurs in a long bone through one of the lesions union is usually strong and radiographs subsequently show that the pale cyst like area of osteitis fibrosa becomes filled with bone Exploration of the neck for a parathyroid tumour is quite unjustified

THYROTOXIC OSTEOPOROSIS (see Hyperthyroidism p 493)

OSTEOMALACIA

Synonyms —Mollities Ossium Adult Rickets

Definition —A generalised disease of the skeleton in which there is defective calcification of osteoid tissue accompanied by an insufficiency of phosphates or calcium salts in the blood The condition may arise in several ways of which three will be described In dietetic osteomalacia it is due to inadequate intake of vitamin D and calcium salts and in idiopathic steatorrhœa to impairment of absorption In the Fanconi syndrome defective tubular reabsorption of phosphates leads to their excessive loss in the urine

Ætiology —Osteomalacia is rare in England It is endemic over wide areas in Northern India Japan and Northern China and occurs sporadically in the Rhine Valley Danube Valley Vienna and certain parts of Italy Switzerland Flanders and the Balkans Heredity plays no part The disease pre eminently affects women and is likely to recur earlier and with greater severity with each successive pregnancy It is a mistake however to suppose that pregnancy is essential in the ætiology The malady is sometimes seen at puberty and is quite well known to occur though rarely in boys and men In the majority of cases the symptoms begin between the twentieth and thirtieth year

Pathology —Rickets and osteomalacia are essentially identical What difference

exists is merely that of age incidence Osteomalacia is adult rickets Morbid anatomists agree that in rickets and osteomalacia the essential abnormality is a deficient calcification of osteoid tissue This deficiency is generalised throughout the skeleton The broad osteoid seams in both diseases are due to deficiency of the calcifying mechanism which should convert osteoid tissue into true bone In osteomalacia the bones throughout the skeleton are so soft that they readily bend and cut with a knife like rotten wood Spontaneous fractures are common The blood chemistry is comparable in experimental rickets of rats in children with rickets and in women with osteomalacia The plasma phosphorus and sometimes also the serum calcium are diminished, and the serum alkaline phosphatase is raised The occurrence of fœtal rickets has been proved in babies born of osteomalacic mothers

Symptoms —Pain is a prominent symptom It occurs especially in the back and thighs is aching in character and is worse in the winter months The pelvis thorax or long bones exhibit deformity in a haphazard way one woman suffers in the pelvis another in the ribs and a third in both Besides the changes in the pelvis marked deformities occur in the chest and spine Severe kypho scoliosis may reduce the height by several inches and cause the head and neck to sink downwards and forwards on to the chest Deformities of the sternum and ribs give rise to marked prominences and depressions in the chest wall Coxa vara and irregularly curved long bones are less common The bones are soft and flexible rather than fragile so that bending is much more common than is spontaneous fracture though both are well recognised The patient develops a characteristic waddling gait and muscular weakness may add to her incapacity In many cases the pelvic deformities interfere with marital relations or with labour Cæsarean section frequently being necessary Tetany is common The teeth are normal The course of the disease may be fairly rapid lasting several months but untreated cases extend over many years The patient then becomes bedridden spontaneous fractures anæmia cachexia and bed sores adding to her discomfort and to the difficulties of nursing

Radiographic appearances —The degree of lack of calcification in radiographs will vary with the severity of the disease and it is therefore important to take radiographs with controls In the slight cases the bones of the patient will be slightly more translucent than those of the control The cortex will be less dense than normal but the bone pattern especially the trabeculation will be accentuated by contrast In the severe examples there will be little or no difference between the density of the bone and surrounding soft tissues and the cortex will appear as a mere pencilled outline The bone pattern will have disappeared the long bones will bend and occasionally show fracture All deformities apart from fracture are the result of weight stress or muscular action The pelvis is tri foliate owing to the thrusts of the heads of the femora and sacrum Lordosis is marked and kyphosis may be present In severe cases the chest and ribs are usually deformed The vertebræ are biconcave having the appearance of fish vertebræ In severe cases the vault of the skull may show numerous areas of uneven translucence varying in size and shape but all fairly clean cut The spontaneous fractures are usually subperiosteal and radiographs sometimes show pseudo fractures These appear as areas of complete translucence running across the bone the edges being quite clean cut and separated from each other by 1 or 2 mm

Diagnosis —The occurrence of pregnancy and the examination consequent upon this lead commonly to the recognition of the pelvic deformity and of the disease which has given rise to it Differential diagnosis from other generalised diseases of the skeleton usually produces no difficulty In hyperparathyroidism there is a high serum calcium a low plasma phosphorus and an increased calcium excretion in the urine In senile osteoporosis the patient suffers from kyphosis and a tendency to fractures particularly of the neck of the femur and the blood chemistry is normal In thyrotoxic osteoporosis the usual signs of hyperthyroidism are present and the

blood chemistry is normal In multiple myeloma the Bence Jones protein is found in the urine in 75 per cent of cases the serum globulin is usually increased and the albumin globulin ration diminished The serum calcium is usually normal but sometimes raised The plasma phosphorus is normal but it rises in cases showing renal insufficiency In radiographs the condition may closely resemble osteomalacia

Treatment —Pure vitamin D is called calciferol because of its power to induce calcification in tissues especially in osteoid tissue It is 300 000 times as potent as cod liver oil weight for weight The good effects not only of calciferol but also of cod liver oil and ultra violet irradiation have been noted both clinically and chemically, since they are capable of raising the serum calcium to normal In cases where tetany is present calcium salts should be administered in addition The diet of a woman suffering from osteomalacia should contain 3 pints of milk a day with plenty of milk puddings, eggs, butter, cheese, green vegetables and even nuts and raisins The dose of cod liver oil should be large up to 2 or 4 oz daily This treatment relieves the pain in 3 to 4 weeks Some cases are refractory and it is then necessary to add 0 5 mg of calciferol to the cod liver oil daily Tetany is rapidly removed by treat ment with cod liver oil and calcium lactate A powder containing at least 10 gm of the latter should be used daily and is best administered fasting with a glass of milk The patient should be exposed to sunlight when this is possible, otherwise treatment by ultra violet irradiation may be used starting with a short exposure to a carbon arc lamp and increasing gradually up to 30 minutes There is no evidence that phosphorus is of any value in the treatment of osteomalacia Where the disease exists in great endemic areas questions of diet and social and religious customs are proving very difficult In large areas of China and India the diet is often deficient in quantity and inadequate in calcium and vitamin D In the high mountain valleys of these countries and in areas of India where purdah is practised darkness adds to the danger by causing further deprivation of vitamin D With regard to China Maxwell states ' We want flocks and herds milk and meat with security of life and property The suggestion has been made that it might be practicable in India and China to dispense calciferol freely at a low price just as quinine is dispensed in malarial districts The relation of ovarian function to calcium metabolism has not yet been settled Osteomalacia gets worse during lactation no doubt because of the great drain of calcium from the body Improvement has been observed after ovariec tomy This operation may act merely by preventing pregnancy and it is presumably just as reasonable to ligate the Fallopian tubes The pelvic deformity may necessitate Cæsarean section

OSTEOMALACIA IN IDIOPATHIC STEATORRHŒA

When osteomalacia occurs in the course of idiopathic steatorrhœa (Gee s disease) the following features may be present fatty stools dilatation of the colon tetany, anæmia skin lesions and infantilism (see p 620) The disease occurs in both sexes and the history nearly always goes back to early childhood The symptoms develop in spite of an adequate diet We must therefore suppose that there is some disturb ance of gastro intestinal function resulting in deficient production absorption or utilisation of one or more essential factors The serum calcium is low and the plasma phosphorus is low or normal The total fat in the stools may reach 40 per cent or more and the bulk of this is unsplit fat The clinical and radiological features are exactly the same as in dietetic osteomalacia An opaque enema will reveal dilatation of the colon In treatment the fat in the diet must be cut down to a minimum and the calcium salts and vitamins kept high Vitamin D must be given in a solid and not in an oily medium The prognosis of this type of osteomalacia is good especially in young people Splinting or even osteotomy may be necessary to correct deformities such as genu valgum The pelvic deformity may necessitate Cæsarean section

THE FANCONI SYNDROME

Synonyms—The de Toni Fanconi Syndrome Hypophosphatæmic Rickets with Renal Glycosuria Osteomalacia with Renal Glycosuria

Definition—A rare form of osteomalacia readily identified by the presence of renal glycosuria and persistent amino aciduria The bone changes are due to excessive renal excretion of phosphates

Ætiology and Pathology—There is impaired tubular reabsorption of glucose amino acids bicarbonate and phosphate probably due to an inborn error of enzyme metabolism It was first described in children by Fanconi in 1931 and was identified in adults and found to be hereditary in 1935 In some cases storage of cystine in the reticulo endothelial system has been found at necropsy Although the association of inhibition of growth and rickets with cystinosis has been known since the work of Lignac in 1924 the relationship between disturbances of cystine metabolism and the Fanconi syndrome is still imperfectly understood The following amino acids have been identified in the urine in abnormally large amounts aspartic acid glutamic acid glycine serine alanine threonine valine cystine leucine tyrosine arginine hydroxyproline and phenylalanine The excessive drain of phosphates through the kidneys leads to a constant low level of inorganic phosphate in the blood which may reach a figure of less than 1 0 mg per 100 ml As a result of this the ossification of osteoid tissue in the skeleton is always imperfect

Symptoms—The disorder is usually discovered in infancy even in babies of 2 months Sometimes it does not make itself evident until adult life In children the skeletal changes of rickets appear and there may be dwarfism and infantilism Loss of appetite polydipsia and polyuria are commonly present The urine shows marked increase of ammonia glucose from time to time and albumin rarely a variety of amino acids can be identified by chromatographic methods (see above)

Radiographic appearances—Radiographs of the bones cannot be distinguished from those of ordinary rickets The changes include absence of calcification of the metaphyses with saucer like splaying of the growing ends of the bones extreme poverty of calcification of the cortex and spongiosa deformities fractures and poorly calcified callus Where infantilism is present the state of development of the bones of the carpus is correspondingly delayed In adults the spine shows well marked osteoporosis individual vertebral bodies being bi concave In radio graphs the pelvis the long bones and especially the bones of the hands and feet are very poorly calcified The ivory corticalis is either reduced to a mere shell or it retains its normal thickness and is greatly reduced in density The spongiosa is deficient owing to disappearance of the smaller spicules and in some places only the coarser trabeculæ are left Fractures and deformities are constant Bowing of the humerus radius and ulna is common and bowing and twisting of the femur is found in many cases Subperiosteal fractures unsuspected by the patient are seen in radiographs in every case The pelvis is usually trifoliate owing to the thrust of the femora and in advanced cases the deformity is grotesque The extreme poverty of calcification ometimes progresses to such a degree that it is difficult in radio graphs to distinguish between bone and soft tissue Nevertheless the skull is often little affected and usually shows only a fine mottled appearance

Prognosis—Fractures of bones recur and may be multiple Extreme deformity of the thoracic cage usually ends in death from broncho pneumonia Though damage to the liver is not an invariable feature of the Fanconi syndrome focal necrosi fibrosis and even primary carcinoma of the liver do sometimes occur even in children Rarely the renal lesion progresses in such a way as to cause nitrogen retention and consequent death

Treatment —The osteomalacia responds imperfectly to vitamin D in large doses A moulded steel spinal support or other orthopædic apparatus may be needed When *there is acidosis due to loss of bicarbonate in the urine* sodium bicarbonate or citrate should be administered by mouth Portal obstruction and hepatic or renal insufficiency will need symptomatic treatment

OSTEOGENESIS IMPERFECTA

Synonyms —Fragilitas Ossium Congenita, Osteoporosis Congenita, Congenital Osteopsathyrosis Osteopsathyrosis Idiopathica

Definition —*A* generalised disease of the skeleton in which the bones are so fragile that repeated fractures occur Multiple fractures may occur *in utero* (pre natal type of Vrolik 1849) or fractures may not occur until after birth (post natal type of Lobstein 1833) The disease is congenital and in some 25 per cent of cases *hereditary Both sexes are affected equally*

Ætiology —This is unknown

Pathology —In both types the basic defect appears to be defective osteoblastic activity The cortex of the bones may be *scarcely thicker than paper* and the trabeculæ of spongy bone are extremely thin In the pre natal type many fractures are seen in some cases practically every bone in the body has been fractured The older fractures exhibit good callus formation In extreme cases especially in the pre natal type, the cranial ossification is so disorganised that the vault of the skull consists of a mosaic of small Wormian bones Congenital hypoplasia occurs in other mesen chymal tissues notably the ligaments and the sclerotics There is no evidence what *ever of vitamin deficiency No* abnormality in the serum calcium, plasma *phosphorus* or calcium output has been demonstrated The plasma phosphatase tends to show a raised value but this is not constant

Symptoms —The *general* health of the patient is good but fractures occur from the most trivial violence or even normal muscle action In the course of time 20, 30 or even 100 spontaneous fractures may occur They are often subperiosteal and cause little pain The patient tends to be short in stature and slender in build As a result of anomalous cranial ossification the shape of the head is often striking A bitemporal protuberance so marked as to turn the ears outwards is frequently observed but protuberances in the occipital and frontal regions are also seen Every bone in *the body may be deformed The limbs are often bowed and of unequal* length Kypho scoliosis distortion of the ribs and sternum and asymmetry of the pelvis all occur Three other defects are commonly found in association with the fragile bones namely leaden blue sclerotics a tendency to dislocation of joints and after the age of 20 years otosclerotic deafness Amongst the adult population affected with blue sclerotics approximately *60 per cent* have an associated *liability to fracture,* approximately 60 per cent an associated otosclerosis and 44 per cent suffer from all three defects Osteogenesis imperfecta sometimes occurs *in an hereditary* form without blue sclerotics

Diagnosis —Severe cases and all those with blue sclerotics are unmistakable In the new born *great* shortening of the limbs may suggest achondroplasia but the skull is quite different Cases of spontaneous fracture in the adult occurring in hyperparathyroidism hyperthyroidism myelomatosis osteoclastic carcinomatosis and neuropathic atrophy of bones really cause no difficulty

Prognosis —Severe cases of the pre natal type are either stillborn *or live only* for a short time In post natal cases the condition proves more severe the earlier the first fracture appears Multiple fractures in the first few years of life may lead to such deformities *that the patient can never* walk and may die before puberty In those who survive the liability to fractures tends to become less before puberty

In general the longer the patient lives the greater will be the improvement, and in many of the adult cases the disability is slight only

Treatment —The utmost care must be taken to avoid the occurrence of fractures Treatment consists in gentle handling and careful splinting Union usually occurs without delay and is firm Dislocations are reduced without difficulty Vitamin D calcium salts and a high calcium diet have no effect on the course of the illness

OXYCEPHALY

Synonyms —Tower Skull, Steeple Head, Sugar Loaf Head Acrocephaly Craniostenosis

Definition —A congenital deformity of the skull due to premature synostosis of the cranial sutures The skull is short from front to back and its vertical diameter is increased Allied forms of craniostenosis are scaphocephaly the boat shaped head and plagiocephaly the obliquely flattened head

Ætiology —This is unknown The disease is more common in males than females It is sometimes hereditary and familial It is usually present at birth but it may develop subsequently up to the age of 6

Symptoms —In its slightest form it attracts attention while in its grosser forms there is no passer by but is shocked by the disfigurement and repelled by its hideous ness The forehead is much increased in height sloping gradually upwards to the vertex with feebly marked superciliary arches The vertex of the skull appears pointed instead of flattened or rounded and a thin bony prominence is sometimes felt in the region of the bregma The hairy scalp may be raised above the normal level and present the appearance of being perched on the top of a cone Viewed laterally the ears appear placed on a lower level than normal Proptosis is present in most cases and it may be so considerable that the eyeballs become dislocated in front of the lids Failure of closure of the eyes especially during sleep may lead to lacrimation and conjunctivitis Divergent squint is common and nystagmus is present in some cases Symptoms arise from insufficient room within the skull for the developing brain There is increased intracranial pressure with headache and sometimes vertigo The condition is compatible with normal intelligence but not infrequently optic atrophy supervenes This is secondary to papillœdema in some 85 per cent of cases In the remainder it is brought about by narrowing of the optic foramen and is of the primary type The sense of smell is often completely lost but taste is affected very rarely Hearing is unaffected The following associated congenital malformations have been described in a few cases webbing of the fingers and toes malformation of ears elbow and shoulder joints and fingers

Radiographic appearances —Radiographs show an increased vertical diameter of the skull with its highest point either at the bregma or somewhere between it and the lambda The anterior fontanelle closes late and its site is marked by a slight protuberance over which the bone is thinned The sutures of the vault are partly or entirely absent but the basal suture between the sphenoid and the occipital bone may be widely open The air sinuses are rudimentary and the middle fossa bulges forward The most characteristic feature is the presence of numerous deep con volutional markings

Prognosis —The optic atrophy whether primary or secondary may advance to complete blindness There is nothing to show that oxycephaly shortens life

Treatment —Anodynes should be used in the relief of headache If the symp toms of increased intracranial pressure become marked and the changes in the optic discs progress decompression may be necessary

DISEASES OF ENDOCHONDRAL OSSIFICATION

ACHONDROPLASIA

Synonyms —Chondrodystrophia fœtalis (Kaufmann), Micromelia fœtalis

Definition —A disease of fœtal life in which defective endochondral ossification makes the bones preformed in cartilage short, but stout and strong

Ætiology —This is unknown Both sexes are affected equally It is hereditary and has been recorded in six generations Several members of the same family may be affected *The condition is unrelated to rickets cretinism syphilis or tuberculosis*

Pathology —The essential abnormality is found in the cartilaginous epiphyses The cartilage does not prepare itself for ossification, which is in consequence so slow that the long bones are too short Since however the periosteum goes on laying down bone normally the bones are stout and strong The membrane bones of the skull are unaffected, so that the calvaria is of normal size Premature synostosis of the cartilaginous bones at the base of the skull leads to shortening and consequent depression of the bridge of the nose The clavicles are not affected The pelvis is distorted and contracted *the sacrum being tilted forwards Extreme lordosis may* be present The costo chondral junctions are enlarged to form a rosary The scapula is so small that the glenoid fossa scarcely holds the head of the humerus

Symptoms —The patient is dwarfed but of normal intelligence The usual height of the adult is about 4 ft The vault of the head is large and the frontal and parietal eminences prominent The face is small and the nose has a depressed and flattened bridge The nostrils are large the lips thick and the lower jaw and chin well developed The teeth are normal The trunk is of normal size but the extremities are much shortened and with the arms at the sides the fingers reach no farther than the great trochanter of the femur The humerus and femur are relatively more shortened than the other bones of the extremities so that the proximal segments of *the limbs show the most marked shortening The arms are muscular and* are held a little abducted from the trunk The hands are short thick and trident shaped the fingers being almost equal in length The lower limbs are thick and often show deep transverse furrows as if there were redundancy of the soft parts This appearance is due to the packing of well developed muscles into the restricted long axis of the limb This muscular development enables the achondroplasic to perform feats which are surprising in one so small He rises from the lying down position by a characteristic springing movement from the legs without any assistance from the arms The curving and enlargement of the ends of certain bones gives rise to bow legs and beading of the ribs The lumbar curve is increased owing to tilting forward of the sacrum and excessive development of the buttocks In consequence the gait has a peculiar *duck like waddling character The genital organs are normal* The fact that the female may become pregnant makes the pelvic deformity of great importance The conjugate diameter is greatly narrowed and it is almost impossible for an achondroplasic woman to give birth to a living child except by Cæsarean section That the disease has existed for something like 5000 years is known from models found in mummies of two achondroplasic gods of ancient Egypt namely Ptah Sokar and Bes In the Middle Ages the attractive antics of achondroplasics made them much sought after as court jesters or dwarfs To day not infrequently they play the parts of clowns at fairs circuses and music halls and sometimes break chains on the stage

Diagnosis —In the new born the great shortening of the limbs may suggest osteogenesis imperfecta but the skull is quite different In childhood the malady is readily distinguished from rickets and congenital syphilis by careful attention to the physical signs Achondroplasia differs from cretinism in that the patient is of

average intelligence and has normal skin hair and voice The pituitary dwarf presents no difficulty because the limbs and trunk are in perfect proportion

Prognosis —The majority of infants suffering from achondroplasia are either still born or die shortly after birth If the child does survive the expectation of life is normal The female achondroplasic faces greater risks in parturition than a normal woman

Treatment —No treatment is of any avail Orthopædic treatment for bow legs is unnecessary The pelvic deformity may necessitate Cæsarean section

DYSCHONDROPLASIA

Three clinical conditions are included under this heading In all of them islands of ectopic cartilage are found giving rise to multiple ecchondromata or enchondromata The three conditions are grouped together because of one feature they have in common namely arrest or perversion of the normal process of endochondral ossification in certain bones This change differs from that seen in achondroplasia only because it is neither symmetrical nor universal Different manifestations of dyschondroplasia may occur in various members of the same family

(i) *Hereditary multiple ossifying ecchondromata* (*hereditary deforming chondrodysplasia diaphysial aclasis or multiple exostoses*) This is a fairly common disease in which multiple bony tumours are found in association with certain other skeletal deformities It is hereditary and may affect several individuals of the same family It is more common in males than in females in the proportion of 3 to 1 It is usually discovered in childhood Palpable bony tumours up to 2 cm or more across are found more or less symmetrically placed near the knee shoulder hip ankle and wrist The scapula ribs and pelvic bones may sometimes be affected The stature is shortened and the limbs may be unequal in length In the majority of cases the ulna and fibula are disproportionately short in relation to the radius and tibia Bowing of the radius ulnar deviation of the hand irregular length of the fingers and valgus deformity of the foot all may occur Sarcoma supervenes in 5 per cent of cases Local exacerbation of symptoms in a patient over 30 years of age may be the first indication of its onset Rarely pressure of an exostosis upon the spinal cord may cause paraplegia or upon a nerve trunk pain or local paralysis Aneurysm has been recorded from pressure upon an artery The radiological appearances are characteristic The metaphysis of the bone affected is broadened and distorted and ossifying ecchondromata with broad bases and pointed tips project from it The cartilaginous cap of the tumour is not seen unless it is calcified The earlier the ecchondroma occurs the nearer to the centre of the shaft will it be Where ecchondromata protrude between adjacent bones such as the tibia and fibula local fusion may occur The ulna is likely to be short and to end in a point articulating with the radius on its mesial aspect but not partaking in the carpal articulation Usually no treatment is required but should it be necessary to remove any particular swelling this is easily carried out.

(ii) *Multiple chondromata* (*Enchondromatosis*) This is a rare disease affecting the bones of the hands and feet Cartilaginous swellings in the fingers and toes begin in childhood and increase in size up to the age of 30 years The swellings are firm elastic rounded and slightly translucent The skin over the larger ones may be tightly stretched and shiny and show prominent veins The hands and feet may become hideously deformed Sometimes a rib near the costal cartilage the sternum the pelvis and the scapula are affected In certain cases the ulna and fibula are disproportionately short as in diaphysial aclasis Spontaneous fractures may occur and sarcoma may supervene after years Radiologically chondromata are seen as rounded eccentric, translucent areas expanding the corticalis interrupting its outline and projecting into the soft tissues Sometimes the swellings are trabeculated and they may

contain dense punctate calcified areas Where operation is undertaken to excise some of the chondromata care must be exercised to avoid spontaneous fracture of the phalanges or metacarpals

(iii) *Unilateral chondrodysplasia (Ollier's disease)* This is a very rare type of chondrodysplasia occurring in children and sometimes familial It usually has a completely unilateral distribution but some cases have only one bone or one limb affected, and others are bilateral *Some abnormality is often first noticed between* the first and second years of life when as a rule, one limb is found to be shorter *than its fellow* The difference in length becomes progressively greater as growth proceeds Deformity may occur either because weight bearing causes bending of the bone or because of the different rate of growth where only one of the paired bones is affected Most patients seem to reach adult life when their symptoms are mainly those of their deformities and sometimes of a secondary arthritis In a small proportion of cases sarcoma supervenes *The diagnosis largely depends* upon examination of radiographs The ends of the long bones show translucent longitudinal striæ interrupted by small pale mottled areas and dark punctate spots *In the areas* affected there is extensive alteration in the pattern of the corticalis and spongiosa but the centre of the shaft remains normal As the child grows older the typical striped appearance disappears and is replaced by dense punctate speckling due to areas of calcification The disease has occasionally been mistaken for osteitis fibrosa but the radiological appearances are pathognomonic Treatment is concerned with the prevention and relief of deformities and proceeds along the usual orthopædic lines *Osteotomy is sometimes necessary Fractures are of fairly common occurrence,* and like the osteotomies appear to unite well

DISEASES OF THE BONE MARROW

MULTIPLE MYELOMA

Synonyms—Myelomatosis Kahler's Disease Plasmacytoma *Hæmatogenous* Myeloma

Definition—A fatal disease characterised by the development of multiple tumours in the skeleton, which arise from cells of the bone marrow It is very rare The bones are affected in the following order of frequency spine ribs, sternum skull scapula pelvis, clavicle humerus and femur

Ætiology—Multiple myeloma is of unknown origin It is a malignant neoplasm of the hæmatogenous marrow occurring *in multiple foci* The disease is related to leukæmia but differs from it in the sharper localisation of the neoplasia the absence of enlargement of the spleen or lymph glands the much smaller tendency for the abnormal cells to enter the blood stream and the frequent appearance of Bence Jones protein in the urine Intermediate forms occur with features of both diseases It is associated with interesting alterations of protein metabolism The disease is sometimes familial It begins typically at the age of 55 and only 10 per cent of cases occur before 40 The sexes are affected in the proportion of 3 men to 2 women

Pathology—Multiple deep red or reddish grey sharply defined tumours are found distributed *throughout the red bone marrow* They are usually a few millimetres in diameter and very numerous Occasionally a tumour may reach a diameter as great as 5 cm They are composed of blood forming cells which resemble plasma cells They erode bone sometimes expand the cortex and cause deformities and spontaneous fractures Rarely a diffuse hyperplasia of the marrow is associated with foci of tumour formation Tumours may also be found outside the skeleton in the tonsils, liver spleen kidneys or sex glands and these *lesions may even precede those*

in the bones The marrow tumours give rise in the urine to the Bence Jones protein which appears as a cloud when the urine is heated to 55 C redissolves at 85 but reappear on cooling It is found in 75 per cent of cases from a trace to a large amount In some cases it appears early in the disease in others late Its occurrence may be continuous or periodic Sometimes a substance allied to amyloid material is deposited in the muscles and in nodules connected with the periosteum bursæ tendon sheaths and joints It is possible that both the Bence Jones protein and the amyloid substance are produced from the breakdown of myelomata The serum globulin is usually increased even as much as to 8 per cent (normal 2 per cent) The albumin globulin ratio may drop from the normal 2 2 to a figure as low as 0 5 The formol gel reaction is positive (see p 267) and there is a very rapid rate of sedimentation of the blood Metastatic calcification while by no means constant has been frequently observed in the kidney lung stomach myocardium and uterine mucosa The serum calcium is usually normal but taking into account the bone destruction which occurs as the result of erosion by the marrow tumours and also the metastatic calcification it is not surprising that high serum calcium values have sometimes been recorded Figures from 13 to 16 mg per 100 ml have been found Those cases with a normal serum calcium have a normal calcium output while those with a high serum calcium have an output up to double the normal Where renal insufficiency complicates multiple myeloma the plasma phosphorus is found to be high and may rise as the kidney condition becomes worse The parathyroids are not enlarged in multiple myeloma

Symptoms —The initial symptom is pain often bilateral in the thoracic abdominal and lumbar regions and sometimes in the neighbourhood of the joints Progressive kyphosis or angular curvature of the spine with loss of total height follows The spine sternum and ribs may be tender on percussion It is unusual for any of the myelomata to be palpable In 60 per cent of all cases spontaneous fracture occurs in the ribs sternum or later in the long bones In no other type of bone tumour does pathological fracture occur so frequently In some cases amyloid masses may be palpable as firm rounded slightly tender subcutaneous nodules more than a centimetre in diameter They are felt especially in the scalp along the spine near the joints and in the musculature particularly that of the pelvic and shoulder girdles There is usually a hypochromic anæmia which becomes aggravated in the terminal stages In a few instances cells of the type which constitutes the tumour enter the blood stream in larger or smaller numbers and it is probable that they can be found in the majority of cases if a sufficiently careful search is made In rare instances the anæmia is of the leuco erythroblastic type Nephritis without hypertension is fairly common The temperature is usually normal but recurring fever has been observed The patient ultimately becomes bedridden and cachectic It seems justifiable on clinical grounds to consider separately what may be called the vertebral form of the disease Here the growth is confined for some time to the vertebral and extradural tissues Moreover death may occur before the growths become widespread and sometimes without the Bence Jones protein having appeared in the urine In this variety the patient rapidly develops signs of a transverse spinal lesion with blockage of the spinal canal The thoracic cord is usually the site of compression and there is focal spinal tenderness Radiographs show destruction of the corresponding vertebral body

Radiographic appearances —In radiographs the marrow tumours are found mainly in the spine ribs sternum and skull They are seen as clean cut elliptical or circular areas of complete translucence set closely together and varying from 1 mm to 5 cm in diameter The large tumours may expand the cortex of the bone affected There is a good deal of generalised osteoporosis throughout the affected bones The spine shows collapse of the bodies of one or more vertebræ The skull is not thickened Spontaneous fractures especially in the ribs are very common

Diagnosis—Once the lesions have appeared in many bones the diagnosis is easily made The age of the patient, multiple involvement of the bones of the thoracic cage spontaneous fracture of a rib Bence Jones protein in the urine progressive anæmia, cachexia and characteristic radiographs make an unmistakable clinical picture Biopsy of a portion of bone or examination of a bone marrow smear from a sternal puncture may reveal the characteristic myeloma cells Secondary carcinomatosis of bones may cause difficulty, especially in cases in which the primary growth is symptom less It is essential to differentiate the disease from generalised osteitis fibrosa (hyper parathyroidism) There is some resemblance in the clinical picture as it affects the skeleton but the presence of the Bence Jones protein and the blood chemistry are characteristic In multiple myeloma the serum calcium is usually normal If it is high it is associated with a high plasma phosphorus, whereas the characteristic effect produced by parathyroid hyperfunction is a high serum calcium with a low plasma phosphorus In osteomalacia the patient is usually a woman in the child bearing period of life, and a good deal of bending occurs in the bones The blood chemistry is characteristic Sometimes in the early stages of multiple myeloma widespread pain in the thoracic abdominal and lumbar regions may lead to a mistaken diagnosis of fibrositis In tuberculous caries of the spine neither the ribs nor the sternum are involved The fact that the Bence Jones protein is found in the urine in an occasional case of leukæmia need cause no mistake In those cases in which nephritis complicates multiple myeloma the albuminuria may cause difficulty The Bence Jones protein may be detected in the presence of albumin by making the urine slightly acid with acetic acid boiling it and filtering while hot using a funnel with a hot water jacket If Bence Jones protein is present the filtrate will become cloudy as it cools

Prognosis—The prognosis is hopeless Death often occurs within 6 months of the onset of symptoms but occasionally a patient survives for 2 years or more Broncho pneumonia cachexia or compression paraplegia with ascending pyelo nephritis are the usual terminal events

Treatment—The patient should be treated by rest in bed, anodynes and suitable splinting when necessary Occasionally deep X irradiation can be used with good effect It alleviates pain and reduces the size of the tumours but it does not retard the progress of the disease It is clearly unjustifiable to explore the neck in search of a parathyroid tumour When the symptoms and signs point to compression of the spinal cord surgical intervention may be worth while Laminectomy reveals a grey or reddish grey extradural mass either pushing the cord backward or encircling it Removal of the mass decompresses the cord and is followed by improvement Deep X irradiation and the wearing of a spinal brace are advised after laminectomy

GAUCHER S DISEASE

In 1922 Pick discovered a gross osseous form of Gaucher s disease It is exceedingly rare The symptoms are pain in the bones spontaneous fractures and some times angular deformity of the spine Limitation of movement of the hip joint is sometimes found In radiographs the bones show patchy osteoporosis A character istic feature is that the lower ends of the femora are widened evenly Both skull and pelvis may be involved Sometimes scattered through the bones there are focal pale rounded areas which expand the cortex These areas are deposits of kerasin, a galactolipin The usual characteristics of Gaucher s disease are of course present (see p 784)

HAND SCHÜLLER CHRISTIAN S DISEASE

The lesions of Hand Schuller-Christian s syndrome (lipoid granulomatosis or xanthomatosis of bones) are not confined to the calvaria the orbit or the sella turcica

(see p 783) Erosions of the maxilla and mandible have been described resulting in loosening or falling out of the teeth Erosion of the petrous bones may lead to a syndrome simulating otitis media and bilateral deafness has been observed Large areas of rarefaction have been described in the long bones of the extremities and in the spine pelvis ribs and clavicles Pain may occur in the bones affected especially the head pelvis and thigh Spontaneous fracture is not uncommon When the pelvis is involved there may be deformity including shortening of one lower limb In some cases the skull escapes entirely diabetes insipidus and exophthalmos being absent Radiologically the deposits of cholesterol ester are seen as irregular clean-cut translucent areas sometimes with a few coarse trabeculæ In order to distinguish the condition from multifocal osteitis fibrosa it may be necessary to excise a portion of bone for histological section The lesions tend to yield temporarily to treatment by X irradiation

DONALD HUNTER

SECTION XVII

DISEASES OF THE SKIN

INTRODUCTION

SKIN diseases are essentially similar in their pathology to diseases of other organs or tissues Congenital anomalies acquired inflammatory degenerative and neoplastic processes affect the skin but the skin is peculiar in that it is exposed to changes of environmental conditions to physical and chemical traumata and to invasion by many different organisms Skin diseases are under the patient s direct observation to a greater extent than occurs with any other organ the lesions are often scratched and rubbed with the result that secondary changes of infection and thickening may be superimposed Self treatment and over treatment with topical applications often have unfortunate results and may mask the original pathological process Many so called skin diseases are in fact physiological reactions which have become fixed or which are excessive and too easily induced, others are pathological modes of reaction of the skin to different stresses

It is assumed that the reader is conversant with the anatomy histology and physiology of the skin and with the descriptive terms used in dermatology A few remarks about the functions of the skin are however relevant to the subsequent discussion of cutaneous pathology

The skin protects the organism as a whole from any harmful environment The epidermis acts as a tough outer covering protecting the layers beneath from excessive insolation, minor traumata and infection the sebum lubricates the horny layer and has bactericidal properties by virtue of its fatty acid content the sweat helps to keep the body temperature steady and emulsifies the sebum and helps to spread it over the body surface If the epidermal barrier against infection is breached the mesenchymal defensive mechanisms come into play with dermal and hypodermal vascular dilatation and the passage of leucocytes and tissue cells into the infected area The cutaneous blood vessels conserve body heat by contracting and dissipate it by relaxing so acting a a thermostat they al o help to keep the blood pressure steady The dermal collagenous and elastic fibres give the skin its tough yet elastic character and enable it at least in youth to conform to the underlying tissues

The sensory end organs in the skin provide for accurate localisation of touch and a delicate perception of slight variations in temperature these set into play a chain of involuntary reflexes and voluntary actions

The skin is an organ of antibody formation a fact made use of in the Mantoux Dick Schick and other tests it is also the organ of vitamin D synthesis from solar irradiation of sterols in the upper layers of the dermis It functions of excretion and of respiration are minimal and need not be considered but its power of absorption is most important some drugs and other chemicals can have serious or even lethal effects by this route

Two other functions of the skin are important to the practising physician In all communities primitive or civilised the skin is the chief organ of display some cosmetics particularly those of a synthetic nature used in civilised communities may cause inflammatory reactions in a few individuals The skin is also the chief organ of emotional expression various feelings being portrayed by alterations in tone of the cutaneous blood vessels in the amount of sweating hair erection etc, with secondary effects on the sebum epidermis and dermis

THE DIAGNOSTIC APPROACH —Bearing the above facts in mind it will be appreciated that the approach to dermatological problems has to be somewhat different from that of internal medicine The ætiology of many skin diseases and reactions remains obscure often several ætiological factors operate together or in sequence Variations of individual reaction to a particular agent for example a drug are marked on the other hand various physical chemical emotional malnutritional and infective noxæ may in the one individual produce eruptions closely similar to each other

In the sections that follow skin diseases have been grouped according to their causes when these are known when the cause is vague or unknown they have been grouped according to the presenting symptom or sign this being the most practical way of considering the differential diagnosis just as it was in the days of Robert Willan

It is essential first to obtain certain historical data in every case Only the patient knows the duration site of onset original appearance and the manner of spread of the malady whether there have been previous attacks and what the past treatments have been with their effects It is legitimate to ask the patient what he believes to be the cause when an irritant contact is suspected The patient is now examined in routine head to foot fashion unless the condition is obviously local and further questioning depends to some extent on the nature and distribution of the lesions Suitable subheadings to the history include family history past history general health personal history domestic and occupational history special attention is directed to racial characteristics and to the presence or absence of evidence of emotional instability

On inspecting the skin it is necessary to decide the nature of the eruption erythematous macular squamous papular vesicular bullous or some combination of these granulomatous nodular or ulcerative hyperpigmented or depigmented and so on This should enable the diagnosis to be narrowed down to a few possibilities The final diagnosis is then attempted from a consideration of the colour morphology and anatomical situation in the skin of any elementary lesion that may be found and from the grouping and distribution of the eruption as a whole and the presence of secondary changes if any Most dermatoses can be diagnosed on clinical evidence alone without the necessity for any pathological tests or biopsies These tests should only be used as ancillary aids in diagnosis prognosis and treatment

SENSORY DISORDERS

Excessive sensibility (hyperæsthesia) without obvious skin changes occurs in some disorders of the nervous system (*q v*) It also occurs in certain skin tumours especially glomus hæmangioma and leiomyoma and in certain inflammatory conditions for example periarteritis nodosa

Lack of sensibility (anæsthesia) is found with certain diseases affecting the nervous system particularly syringomyelia leprosy tabes dorsalis peripheral neuritis and hysteria

In syringomyelia there may be anæsthesia with trophic changes in the skin of the fingers (Morvan s disease) The shiny anidrotic skin is liable to become infected leading to destructive changes The discrimination between heat and cold is lost and the sensation of touch diminished or lost. Burns may easily occur

In leprosy depigmented or lupoid anidrotic anæsthetic or paræsthetic areas of skin may be found loss of touch heat and cold being the earliest sensory changes

In tabes dorsalis perforating ulcers of the foot are the commonest manifestations of the sensory disturbance

In diabetes and other forms of peripheral neuritis glossy skin and perforating ulcers may occur sometimes complicated by arteriosclerotic ischæmic effects

In hysteria glove and stocking anæsthesia is a common symptom and the presence of Charcot s triad of palatal anæsthesia, conjunctival anæsthesia and suggestion anæsthesia is strong circumstantial evidence suggesting that a dermatosis is being hysterically produced or maintained

Abnormal sensibility (paræsthesia) occurs in a large number of skin diseases as itching (pruritus)

PRURITUS

This term is used to describe general or local itching of the skin in which there is either no obvious local cause or physical sign or in which such physical signs as exist are secondary and due to rubbing (lichen simplex) scratching excoriation, infection or over treatment

GENERAL PRURITUS

Ætiology and Pathology —Generalised itching more commonly occurs in the elderly and is thought to be due to arteriosclerotic changes in the central nervous system There may be some atrophy of the skin but this is often seen without pruritus and it probably has no connection with the symptom

Histologically no changes are observed in the skin except possibly some degree of coincidental atrophy and the effects of physical damage

Clinical Picture —The patient complains of itching and tingling of the skin, particularly when getting dressed or undressed or a few minutes after getting into bed Hot baths or proximity to a fire aggravate the condition Loss of sleep increases the sense of irritability and helps to establish a vicious circle There may be no physical signs even when the patient complains bitterly of the distress and loss of sleep or there may be scratch marks, excoriations and areas of lichenification eczematisation and even some degree of infection

Course and Prognosis —In the idiopathic senile variety the prognosis as regards cure is poor, though longevity is not affected In all other varieties the prognosis depends on the cause

Diagnosis —General pruritus may be a symptom of diabetes jaundice uræmia or gout of intoxication by cocaine or opiates including codeine, of leukæmia or Hodgkin s disease of cutaneous reticulosis or carcinomatosis Pediculosis and scabies must be excluded itching around the shoulders may be due to *pediculosis capitis* or *corporis*, the underclothes should always be inspected for lice and nits particularly at the seams louse infestation is more often secondarily infected than is idiopathic pruritus The patient must be questioned as to the occurrence of whealing there may be none at the time of examination or dermographism may be demonstrable General pruritus may be of emotional origin especially when there is frustration or deprivation of affection If there are excoriated papules the diagnosis of dermatitis herpetiformis must be considered

Treatment —The patient if retired should be kept fully occupied so as to distract attention from the skin as much as possible Sudden changes of temperature must be avoided Baths should be pleasantly warm not hot and 4 oz of bicarbonate of soda may be added to a 25 gallon bath to relieve itching Woollen underclothing should not be worn in direct contact with the skin Condiments strong hot tea and coffee and over indulgence in alcohol must also be proscribed Sedatives such as phenobarbitone promethazine hydrochloride or butobarbitone are useful, and in milder cases a bromide and valerian mixture Opiates should not be given

For local treatment if the skin is dry hydrous ointment is useful or equal parts of glycerine of starch and lanolin In other patients a lead and calamine lotion or a

lead and glycerin lotion can be used but tar phenol menthol antihistamines and benzocaine derivatives are best avoided

LOCALISED PRURITUS

This may occur without physical signs or friction may produce the condition known as lichen simplex (*q v*) This is of variable appearance according to its situation The commonest sites are the scalp the back and sides of the neck the eyelids brows or perioral region behind and above the ears the elbows wrists or palms the external genitalia the medial aspects of the thighs the lower parts of the calves and the feet

ANOGENITAL PRURITUS

This may occur as pruritus ani in either sex as scrotal and perineal pruritus in the male, or as vulvar pruritus or combined anal and vulvar pruritus in the female

PRURITUS ANI

Pruritus ani is often present without physical signs if any signs are present they may be either the cause or the effect of the symptom

Ætiology—Often the itching starts from some transitory cause but continues after this has been removed in part owing to a vicious circle of scratching and further itching and in part owing to the relief of emotional tension that seems to be provided in some individuals from this practice Anal irritation may be due to rectal anal or cutaneous conditions to diabetes or to drug intolerance Proctitis with irritating discharge is an occasional cause Threadworms in the rectum pass into the anal canal for ovideposition and cause intense itching Piles and anal fissures are other common causes but cutaneous tags resulting from fibrosed piles should not be removed in an attempt to give relief On the skin lack of cleanliness monilial and fungous infections and *Phthirus pubis* infestation may be responsible or the condition may have arisen from sensitisation to local applications from drugs such as phenolphthalein taken internally from the disturbance of intestinal flora and the encouragement of monilia by the use of antibiotics such as chlortetracycline or chloramphenicol or rarely from skin diseases such as lichen planus Patients with pruritus ani often suffer from localised hyperidrosis which aggravates the condition by the discomfort it causes and by its encouragement of fungous and other infections In resistant cases without physical signs or with lichenification an emotional factor may be the most important this may take the form of inadequately expressed rage and aggression or it may be symptomatic of a passive homosexual tendency

Clinical Picture—The skin may look normal or there may be scratch marks and deep furrowing and ridging from lichenification There may be a sodden condition of the anal funnel or there may be a patch of lichen simplex 2 or 3 in to one side of the anus The psychogenic form may be accompanied by a tendency to exhibitionism shown by the wearing of effeminate clothing as well as by an exceptional enthusiasm for being repeatedly examined by the doctor

Treatment—If no obvious cause can be removed the treatment is symptomatic by bland local applications sedatives and in the most resistant cases X irradiation in exposures of 50 r or 75 r on up to four occasions at weekly intervals When lichenification is present thorium X applications may prove as effective as X rays and they carry no serious hazard of post irradiation skin changes The constant application of first one and then another remedy to the itchy anus must be discouraged as only increasing introspection A good standard of cleanliness is important but medicated soaps or antiseptics should not be used The skin should be dried carefully without friction from a towel and a dusting powder of talc and boric acid applied

The best local applications are hydrous ointment or a thin zinc cream to which 1 0 per cent of phenol may be added, or if any infective element is present magenta paint may give good results Antihistaminic creams and benzocaine derivatives are best avoided Good results are being claimed from the use of hydrocortisone ointment

Aperients, particularly phenolphthalein and aloes, may aggravate the condition and the patient should avoid them or use only liquid paraffin Strong coffee and condiments are best avoided

Psychoanalytical procedures are rarely of value in pruritus ani nor are nerve undercutting operations or anæsthetic injections a logical or effective procedure

SCROTAL AND PERINEAL PRURITUS

Here a fungous cause may be apparent There may be hyperidrosis Friction from clothing may aggravate the condition and sensitisation to dyed material may start it Pruritic scrotal dermatitis may also arise with diets deficient in protein iron and vitamin B complex but in the majority no local cause can be determined In psoriasis and lichen planus scrotal lesions may be present but they are rarely more than the local manifestations of the general disorder Lichen simplex is often observed with or without eczematisation and infective changes

Dietetic adjustments and antifungous measures may be indicated and disorders such as seborrhœic dermatitis lichen planus and psoriasis are treated on general principles For lichen simplex in the perineum or on the scrotum bland local applications such as oily calamine lotion or hydrous ointment are preferable to antihistaminic creams which have a tendency to sensitise the skin Local anæsthetic (benzocaine) applications have strong sensitising properties and may cause a severe eczematous dermatitis which adds to the patient s distress Thorium X in spirit in a concentration of 1500 e s u per ml, applied at fortnightly intervals on up to six occasions may help X rays may be used in fractional doses but are best avoided on the scrotum If they are used here it is wise to use very small (33 r) individual exposures up to a total of 100 r only

In addition to these local measures an attempt should be made to relieve sexual maladjustments if present This is more likely to succeed with scrotal than with perineal or anal pruritus

PRURITUS VULVÆ

This term is sometimes applied to dermatoses of the genitocrural region and medial aspects of the thighs, as well as more correctly, to strictly vulvar conditions

Ætiology and Pathology —The causes include vaginal discharges due to trichomonas or monilial infections, nutritional deficiencies drug intoxications particularly from oral chloramphenicol or chlortetracycline threadworms (in children) glycosuria psychosexual difficulties contact sensitisation to contraceptive jellies vaginal douche solutions or to the rubber of contraceptive appliances to lack of cleanliness or to the excessive use of antiseptics to *Phthirus pubis* infestation Localised dermatoses that may be responsible include psoriasis seborrhœic dermatitis lichen planus atrophic senile vulvo vaginitis Bowen s precancerous dermatosis but in all these conditions as well as in lichen simplex there is a possibility of the dermatosis being the result of friction rather than the cause of the pruritus A most intractable form is that due to *lichen sclerosis et atrophicus* this is an atrophic sometimes bullous condition of the vulva perineum and perianal skin often with similar lesions elsewhere

Clinical Picture —There may be no abnormal physical signs or there may be lichenification excoriation boils or impetiginous lesions or a superimposed mixed contact and infective dermatitis resulting from faulty treatment

Treatment —This depends on the cause and may consist of the control of diabetes or of a trichomonas infection the relief of an emotional conflict the removal

of an offending drug the avoidance of a contact irritant or the provision of an adequate diet A drug such as phenolphthalein may cause a fixed erythema at the vulva with pruritus or drugs such as chloramphenicol or chlortetracycline may by removing competitors encourage multiplication of monilia the pruritus in these circumstances being caused by a monilial vulvo vaginitis or by vitamin deficiency from the destruction of intestinal organisms having the property of synthesising vitamin B

Ample sedation with barbiturates is necessary to prevent the establishment of a vicious circle of friction lichenification and infection and more friction It must be remembered however that barbiturates can though rarely themselves cause pruritus vulvæ

Local treatment depends on the type of reaction observed If there is any infection magenta paint or Vioform cream are usually effective in the less severe forms due to monilia and *Staphylococcus saprophyticus* and a wide spectrum antibiotic such as chlortetracycline oxytetracycline or chloramphenicol in frankly pustular furuncular or impetiginous forms A 1 0 per cent solution of cetrimide is useful as a cleansing agent For vulvar boils the application of a 75 per cent industrial spirit with 1 per cent brilliant green and 0 1 per cent mercuric chloride is useful For lichen simplex hydrous ointment zinc cream or ether soluble tar paste (Martindale) may be used Antihistaminic creams are probably no more effective than the base in which they are incorporated and their use carries with it some risk of the development of cutaneous sensitisation Benzocaine anæsthetic applications are contraindicated because of their powerful sensitising properties The use of œstrogen creams is restricted to cases of senile vulvo vaginitis with atrophy For pruritus vulvæ with lichenification thorium X in a strength of 1500 e s u per ml of spirit applied fortnightly is sometimes effective as is X irradiation given in exposures of 75 r weekly on up to four occasions For Bowen s disease excision is preferable to radiotherapy owing to the relative radio insensitivity of this dermatosis

Psychogenic forms may respond to the relief of conflicts over sexuality these usually being due to a guilty liaison or to fear of pregnancy venereal disease or cancer

PRURIGO

Prurigo is a term used for a group of intensely itchy conditions in which the predominant physical signs are lichenification and excoriated papules Lichenification is produced by friction and presents as terracotta thickened skin with accentuation of the contrast between the normal diamond shaped elevations and intervening furrows Prurigo papules are ill defined obtuse elevations with excoriated tops caused by trauma from the finger nails In some forms a contributory factor may be erection of the hair follicles (horripilation) in response to various stimuli

Ætiology and Pathology—The ætiology of these various disorders will be dealt with individually

Histologically there is hyperkeratosis thickening of the granular layer and acanthosis with elongated rete ridges In the dermis there is an inflammatory infiltrate Areas in which the epidermis has been removed in part or in its full depth may be seen covered by blood scabs or by infected scabs

LICHEN SIMPLEX CHRONICUS

(PRURITUS WITH LICHENIFICATION NEURODERMATITIS CIRCUMSCRIPTA NEVRODERMITE)

Ætiology and Pathology—The sense of itching in this condition is usually central in origin and brought about by frustrated anger or libido or a trivial local irritant may operate in the first place and the vicious circle of itching rubbing lichenification itching be brought about This primary form has to be differentiated from lichenification developing on contact dermatitis a phenomenon not unusual where

compensation claims await settlement or where there is some other significant emotional factor in addition to a contact cause for a dermatosis In both primary and secondary forms hysterical traits are often apparent

Histologically there is slight hyperkeratosis and marked acanthosis, with a non specific infiltrate in the dermis

Clinical Picture —A patch of lichen simplex is usually oval and if on a limb lies in its long axis The colour is red or reddish brown and the edge fades off gradu ally into the normal skin without outlying " satellites The surface shows an accentuation of the normal skin pattern, creases being increased in both depth and width, and the interposing lozenge or diamond shaped areas more obviously elevated above the creases than in the normal skin These areas are often shiny and resemble grouped papules of lichen planus There may be a fine scaling or warty thickening If scratching is carried out as well as rubbing excoriations and blood scabs may be visible There is usually marked pigmentation but occasionally depigmentation occurs Lichenified skin is thickened and inelastic tending to become fissured and secondarily infected with erysipelas, impetigo or boils The sites most character istically affected by lichen simplex are the nucha the sides of the neck and the supra clavicular regions the ulnar aspects of the elbows, the hands the external genitalia the anal and perianal regions the inner and outer thighs, and the antero lateral aspects of the calves but other sites may be affected

Lichen simplex is modified in appearance in certain situations On the scalp scabbed excoriations are often seen or diffuse redness and profuse coarse scaling even with collarettes of coarse asbestos like scaling for a few millimetres up the hair shafts—the so called ' fausse teigne amiantacee At the nape of the neck an oval area is usually superficially excoriated with grey scales and light crusting A mild infection may be superimposed On the brows the hairs are broken off short On the palms dyskeratosis dominates the picture and accentuation of the skin pattern is inconspicuous In the flexures the hyperkeratotic skin becomes fissured sodden and whitened resembling leucoplakia The sufferer from lichen simplex may become agitated and start to rub the lesions during the interview when enquiry is made into relevant personal matters

Course and Prognosis —The malady may persist indefinitely or disappear with out treatment its relief depends on abatement of the emotional tension Sometimes this is not possible sometimes if the patient and the source of the tension can be separated the condition may clear without other treatment

Diagnosis —The diagnosis from lichenified dermatitis of external origin is often difficult Usually with lichenified dermatitis there is a history of a more widespread eruption which has finally become localised perhaps in the antecubital regions

Lichen planus may simulate lichen simplex but there are usually some discrete lesions to be found which clarify the diagnosis Lichenoid plaques on the legs how ever may be due to lichen simplex lichen planus or (rarely) lichen amyloidosis their differentiation may only be possible by biopsy

At the nucha, lichen simplex may resemble seborrhœic dermatitis and psoriasis, but the circumscribed pattern is not typical of the former and the absence of silvery scaling or of psoriasis elsewhere renders the latter diagnosis improbable The presence of pediculosis or of hair dye dermatitis must be excluded On the palms psoriasis and dyskeratotic contact dermatitis have to be excluded on the evidence of the history and the presence or absence of psoriasis elsewhere At the flexures leucoplakia can be excluded because it only occurs on mucous surfaces but lichen simplex of the mucosal aspects of the labia majora and of the labia minora may be accompanied by leucoplakia

Treatment —The treatment of lichen simplex is essentially the relief of the related tension state If as often happens this is not possible an attempt has to be made to break the vicious circle with general sedatives and local applications

Barbiturates are most useful for this purpose for example phenobarbitone gr ¼ to 1 twice a day and butobarbitone gr 3 to 4½ in the evening or a bromide and valerian mixture may prove useful and promethazine hydrochloride 25 mg in the evening for its antipruritic action Occasionally the draught of paraldehyde 1½ fl oz is indicated as a quick acting sedative for use in the middle of the night Amphetamine sulphate 5 mg after breakfast is useful when there is depression and helps the patient to obtain relief by deeds or words *in place of harmful and useless emotions*

Locally tar is of great value in the form of the solution of coal tar 2 to 6 per cent in zinc paste or the more elegant ether soluble tar paste (Martindale) may be used At the nucha it is better to incorporate the tar in the ointment of wool alcohols and when the skin is markedly thickened the solution of coal tar can be applied neat once a day with considerable relief At flexures and the anogenital region tar cannot be used with safety and magenta paint makes a valuable substitute partly no doubt from its phenol content and partly from its powers of controlling secondary fungous infections Occlusive dressings are not so effective as might be expected because *they may give the patient a feeling of guilt and frustration from the loss of the emotional* relief (*onanisme prurituque*) that rubbing these lesions provides

X rays in a course of three or four exposures of 75 to 100 r each time are often invaluable thorium X too 1500 e s u per ml is often helpful particularly at hairy sites or if the patch is of a shape and size not easily covered by an X ray applicator Thorium X is applied in spirit or as a varnish and the affected area should not be washed for the next 72 hours The patient should be warned that considerable pig mentation may develop at the treated site and persist for some months

The patient should avoid hot baths and proximity to fires and try to avoid emotional heat from the life situation as a whole Adjustments so as to avoid difficult personal contacts may be necessary and prove highly effective

PRURIGO OF BESNIER

(Flexural Prurigo Atopic Dermatitis Asthma Hay Fever Prurigo Syndrome Pruriginous Facial Eczema etc)

Prurigo of Besnier is an itching condition affecting in particular the flexures and the face it usually begins in infancy and may alternate with or more rarely be accompanied by asthma or hay fever

Ætiology and Pathology—The fundamental abnormality is spasm of plain muscle from many relatively trivial stimuli which would have little or no effect on the majority The spasm may affect the bronchioles causing asthma the vessels of the nose causing vasomotor rhinorrhœa and the skin causing gooseflesh and vasoconstriction Sweating is often excessive

Inheritance and the early environment both seem to be of importance in the ætiology but the latter seems more significant than the former Those affected are of average intelligence but are excitable and prone to feelings of insecurity and are often maladjusted to their parents particularly the mother (the so called maternal rejection factor) Threats to security or to loss of affection are the most significant and obvious of the many factors that bring about exacerbations Breakdowns may occur with changes of school or occupation or at times of engagement marriage or bereavements Other factors include changes of temperature or of humidity air borne injected or ingested allergens rough clothing drugs and infections The pruriginous individual reacts to everyday stimuli with a mechanism designed for emergencies Thus pollens danders and household dusts may cause bronchial spasm or vasomotor rhinorrhœa Stroking the affected skin causes a white line to develop in 15 seconds the usual red line does not follow at unaffected sites the normal reaction of white line followed by red may be observed Cutaneous infections in *these individuals tend to become generalised* in part because of the scratching that

helps dissemination Thus, pruriginous individuals may get generalised staphylo derma generalised herpes or widespread vaccinia

Clinical Picture —Besnier s prurigo presents as one of the forms of infantile eczema (*q v*) It may begin as early as the second month as a papulo vesicular and erythemato squamous condition involving parts easily reached by the infant—the face, neck, antecubital regions wrists hands, popliteal spaces calves ankles and feet The trunk may escape entirely or it may show a patchy ill defined faintly pink papular and scaly eruption The lesions may be exudative infected or lichenified

The infant periodically indulges in orgies of rubbing particularly in the evening when *bored, frustrated or tired, and with determination overcomes any attempt to* restrict this practice The face may be rubbed by rotation to and fro on the pillow even if the arms are tied The condition usually becomes milder when the child starts to walk and to do things for itself It may disappear for several years but there is usually a recurrence at puberty and the prurigo is then more strictly localised to the bends of the elbows and of the knees the hands and wrists the face and neck and sometimes to the genitocrural region and to the feet The affected areas show lichenification and excoriations The condition may persist well into adult life (though it usually gets less severe after 20 years of age) with exacerbations from exposure to heat anxieties and an ever varying pattern of contact sensitisers or air borne allergens (if the results of patch and scratch tests can be accepted as valid in these individuals) Sometimes the first occurrence is in adult life and engagement, marriage or a bereavement usually precedes the dermatosis

Xeroderma is often coexistent with Besnier s prurigo and modifies the picture Cataracts are a serious complication in some cases which persist into adult life They are believed to be congenital but friction applied to the eyelids may well play a part in their maturation

Course and Prognosis —This depends upon the possibilities of dealing with the causal factors If they cannot be eliminated the malady may persist indefinitely

Diagnosis —The malady has to be differentiated from contact eczematous dermatitis especially when complicated by lichenification In prurigo the essential lesion is not a papulo vesicle but is a prurigo papule an obtuse elevation of a brown or dusky hue often with an excoriated top or if these elementary lesions are not discernible lichenification dominates the picture

Besnier s prurigo involving the face (pruriginous facial eczema) has to be differentiated from actinic dermatitis and from eczematous dermatitis of the face caused *by air borne or hand transferred agents* The *former* affects the forehead nose and malar ridges and other parts exposed to light The latter affects particularly the eyelids and perhaps the skin of the sides of the neck

Treatment —The treatment of Besnier s prurigo is very much that of the whole patient with his characteristic personality and his personal problems rather than the management of his skin condition by itself A change of attitude and co operation on the part of the parents is equally important If a steadier level of affection in a calmer home atmosphere can be made to prevail all well and good If not a temporary removal from the unfavourable and often tense atmosphere is the second best choice *This may entail a period in hospital or in a convalescent* home and for some cases special residential schooling facilities are ideal

Apart from these procedures treatment is mostly symptomatic by bland local applications such as calamine liniment and general sedatives in ample dosage bearing in mind that sufferers from prurigo usually tolerate barbiturates well and need doses larger than the average to bring about quiet and sleep and freedom from scratching Antihistaminic drugs with antipruritic properties for example promethazine hydrochloride are also valuable Chlorpromazine 25 mg t d s or methylpentynol (Oblivon) 250 mg t d s is sometimes helpful The pruriginous patient needs to be kept fully

occupied either with suitable manipulative toys in childhood or by manual work in adult life

For the worst cases in patient treatment is invaluable sedation can then be used in larger doses and nonspecific measures tried such as fever therapy with T A B intravenously in doses of 25 million 50 million and 100 million organisms at 5 day intervals (for an adult) For localised patches thorium X or X irradiation is sometimes indicated Intravenous injections of corticotrophin 50 mg 8 hourly will bring about a partial remission but this treatment is advisable only in exceptional circumstances

Hydrocortisone ointment has recently been reported to be highly effective in relieving the local manifestations of this malady

DISSEMINATED NEURODERMATITIS

This term is used for extensive and severe examples of Besnier s prurigo and other widespread lichenified and pruriginous eruptions in which no contact toxic or reticulotic cause can be discovered but in which the malady appears to indicate a maladjustment to the environment particularly in circumstances of deprivation of occupational activities bereavement sexual frustration and unwantedness It affects adults of all ages

PRURIGO OF HEBRA (PRURIGO FEROX)

A chronic itchy disease starting as urticaria and persisting indefinitely Two forms are recognised prurigo ferox and prurigo mitis

Ætiology and Pathology —Inheritance is an important factor but whether this consists of the inheritance of an abnormality of the skin or a low level of intelligence is not clear probably the second is the more important

Clinical Picture —The condition usually begins in the first or second years with a polymorphic eruption of scratch marks erosions lichenification and papular urticaria The malady gradually becomes localised to the limbs particularly to their extensor surfaces Later prurigo nodules develop and the urticarial component fades

As years pass the picture is of extensive excoriations lichenification and pigmentation with scarring and thickening of the skin and freedom of the flexor aspects of the joints The lymph nodes in the axillæ and groins are enlarged The trunk neck and face may be affected The malady is rare in the British Isles

Diagnosis is from xeroderma and from other itchy diseases of the skin including crusted scabies

Course and Prognosis —Prurigo mitis may improve at puberty but in prurigo ferox the prognosis is unfavourable the malady persisting in spite of treatment Infection may occur

Treatment is symptomatic by bicarbonate of soda or tar baths antipruritic applications such as 2 to 4 per cent of solution of coal tar in zinc cream or paste and adequate sedation by bromides barbiturates or antihistaminic drugs A period of removal from the home surroundings to hospital convalescent home or residential school is often useful

PRURIGO NODULARIS

This is a rare malady and may in fact be a variant of lichen planus (*lichen obtusus corneus*) differing from *lichen planus hypertrophicus* by reason of the large obtuse dome shaped nodules affecting the extensor surfaces of the forearms and legs whereas *lichen planus hypertrophichus* is more plaquelike and usually localised to the calves and ankles

SECRETORY DISORDERS

Sweat secretion may be excessive, diminished or suppressed (hyperidrosis hypoidrosis and anidrosis)

Sebum secretion may be excessive (seborrhœa) or diminished (xeroderma ichthyosis) *Sebum secretion* is qualitatively altered in "seborrhœic dermatitis without there necessarily being any quantitative changes "Seborrhœic dermatitis may occur with an average sebum flow or with seborrhœa or even with xeroderma It is better designated "infective dermatitis

HYPERIDROSIS

Generalised sweating normally occurs from heat, exertion fear, febrile and toxic states Certain central nervous system lesions hyperthyroidism and acromegaly and some drugs (acetylcholine pilocarpine) can also cause sweating Adolescents and young adults are affected more often than children or older people by excessive sweating from anxiety the obese suffer most from heat and exertion

In localised hyperidrosis the sites most commonly affected are the palms and soles, the axillæ the anogenital region or the centre of the face On the palms and soles there is often also a tendency to perniosis Involvement of the hands may interfere with working capacity, owing to soiling of paper and other materials handled Sweaty feet provide damp dark poorly aerated conditions which are ideal for the growth of saprophytic organisms Sweat acid when secreted becomes alkaline as it decomposes and this further encourages the growth of pathogens and facultative pathogens, both bacterial and fungous The decomposing sweat often has an offensive odour (bromidrosis) and may become coloured from the proliferation of chromogenic bacteria (chromidrosis)

Excessive sweating predisposes to contact dermatitis from water soluble irritants Dermatitis in the rubber industry is more common in sweaty individuals the sweat leaching out potentially irritant antioxidants and other preservatives from the rubber Similarly, dermatitis of the axillary folds occurs from dyed clothing or from dress protectors

Perianal sweating often becomes complicated by maceration and monilial or other fungous infections

Axillary hyperidrosis is a serious inconvenience to many women because it may cause discolouration and rotting of fabrics bromidrosis and other social embarrassments Offensive axillary odour (bromidrosis) is entirely due to bacterial decomposition of the sweat the axillary apocrine sweat being without odour when first secreted

Sweating of the centre of the face may be caused in some individuals by eating hot or spicy foods

Excessive sweating in fever may cause the eruption of raindrop like vesicles (*miliaria crystallina sudamina*) situated in the horny layer

Treatment—The uncovering and removal of any emotional cause that may be present is essential for cure otherwise treatment is largely symptomatic A bromide mixture with belladonna to the limit of tolerance may be used to give temporary relief but is not a practical method for prolonged use Phenobarbitone may be more effective In severe cases a trial of ganglion blocking agents such as pentolinium tartrate is justifiable The fluid intake should be as small as possible consistent with the relief of thirst Frequent tepid baths should be taken and the whole body or the affected parts liberally dusted with a boric acid and talc or salicylic acid powder the latter being especially useful on the feet To prevent or combat infection and to minimise bromidrosis foot soaks in a 1 in 6000 solution of potassium permanganate

are useful Coarse woollen socks and rubber soled or tennis shoes should not be worn The socks should be of a cotton material and should be changed at least once a day For the axillæ a 1 in 80 solution of aluminium acetate (Burow s solution diluted 1 in 10 with water) is the most effective remedy The axillary hair should be kept closely shaven to make washing easier Sympathectomy is not advisable for a malady often emotionally produced and X ray treatment, if it is to be effective necessitates a dosage which exposes the patient to the risk of later irradiation effects on the skin

HYPOIDROSIS

Diminished sweating occurs in myxœdema congenital ectodermal defects extensive scarring diabetes renal disease and some cachectic states also in some skin diseases particularly xeroderma scleroderma and in the senile skin or in the atrophic skin following the administration of liquor arsenicalis or the excessive use of X rays or too much exposure to the sun In other skin diseases with pathological scaling partial obstruction of the sweat ducts may cause hypoidrosis

ANIDROSIS

Cessation of sweating occurs in the anæsthetic skin areas of leprosy after sympathectomy and sometimes in poliomyelitis Sweat suppression may occur in hot humid climates as prickly heat (*miliaria rubra*) and as tropical anidrosis (*miliaria profunda*) In temperate climates a similar condition may be caused by hot humid working conditions and by exposure to moderate heat after having suffered and perhaps partially recovered from some forms of contact dermatitis for example that due to cement dust

Prickly heat is peculiar to the white races Its causes are believed to be the wearing of clothes and the use of spirit powders and too much soap on the skin in humid hot climates also the seborrhœic type of skin with follicular vulnerability to infection The qualitative sebaceous deficiency leads to the formation of keratin rings at the ostia of the sweat ducts These rings act as plugs and the dammed up sweat bursts out from the ducts causing disruption of the adjoining epidermal cells rupture of the duct lower down may cause an inflammatory reaction in the dermis Clinically there are itchy red papules of prickly heat (*miliaria rubra*) and follicular pustules (*ostio folliculitis* Bockhart s impetigo) due to infection of the contents of obstructed ducts Recurrent attacks of prickly heat may lead to destruction of the intra epidermal portions of the sweat ducts further exposure to heat and humidity may then lead to *miliaria profunda* with vesicles resembling sago grains in the dermis causing non itchy tropical anidrosis which may go on to heat stroke

Adhesive plaster skin reactions are more often due to sweat duct obstruction and infection than to eczematous hypersensitivity It usually starts 48 hours or more after the application of the plaster It is likely that other forms of dermatitis for example those due to dress protectors rubber cement etc are in part due to sweat duct irritation and obstruction

Prevention and Treatment—An attempt should be made to maintain an oily film on the surface of the skin in order to replace any sebaceous deficiency For this purpose anhydrous lanolin or the ointment of wool alcohols may be used The patient should be advised against the use of degreasing and dehydrating substances on the surface of the skin and should wear loose mesh cotton underwear

DYSIDROSIS (see Pompholyx p 1220)

SEBORRHŒA

Excessive oiliness of the skin may occur from puberty onwards and is due to *hormonal (androgenic) influences*, it usually diminishes with advancing age It is more common in the coloured races and may show a familial incidence amongst white people It affects the regions with most sebaceous glands, the scalp the face the nasolabial folds the chest and the back The skin is greasy, thickened, muddy coloured and with patulous follicles from which semi solid sebaceous material is extruded There is often a tendency to premature baldness of masculine type while other areas, such as the beard and chest grow tough, coarse hair *Acne vulgaris* is a common complication of seborrhœa Keratinous plugs at the pilosebaceous follicles cause retention of sebum and inflammatory changes of acne papules and pustules Infection of the seborrhœic skin with facultative pathogens may cause infective (seborrhœic ') dermatitis or *infection with more virulent organisms may* cause impetiginised seborrhœa or furunculosis The seborrhœic skin is unduly susceptible to fat soluble irritants, hence the application of ointments containing antiseptics may cause a chemical folliculitis and dermatitis Seborrhœic individuals have a tendency to develop rosacea

Treatment—The diet should contain ample protein vitamins and minerals and should not contain an excess of fats and carbohydrates Frequent washing with *soap and water is essential Sulphur compound lotion may help to diminish seborrhœa* and to control any associated acne or infection

XERODERMA

In xeroderma and its more severe form ichthyosis the skin is abnormally dry *with a diminished secretion of sebum and to a lesser extent of sweat* There is also a thickening of the horny layer sometimes with preference for the pilosebaceous follicular orifices (*Keratosis suprafollicularis*)

Ætiology and Pathology—The disease is inherited apparently as a dominant factor affecting both sexes and often several members of one family It is usually noticed soon after birth and may be present at birth Histologically there is hyper keratosis especially at the pilosebaceous ostia and an absence of the granular layer The prickle *cell layer is thin The sebaceous glands are few and small* but the sweat glands are not obviously diminished

Clinical Picture—In the milder cases the skin on the extensor surfaces of the limbs and body is dry and rough, with a slight branny scaling The flexures appear normal On the extensor surfaces of the limbs the hair follicles are prominent with small horny spines projecting The hair is dry and lustreless and breaks easily It may be sparse In severer cases fish like adherent grey scales cover the whole body *The skin is rough and even the face is affected to some extent* *Ichthyosis hystrix* is a form of hard nævus occurring in lines or bands and has no relation to ichthyosis Xeroderma often accompanies Besnier s prurigo

Course and Prognosis—The dry unoiled skin cracks easily and from its deficiency of sebum is susceptible to bacterial infection Xerodermatous *individuals* have to be prevented from taking up unsuitable occupations Excessive contact with soaps detergents and fat solvents are all likely to be harmful exposure to cold weather aggravates the condition the glandular activity then being minimal on the other hand extreme heat may lead to heat stroke owing to the inability of those suffering from severe xeroderma to lose heat adequately by sweating Xerodermatous individuals should be in clean dry work in an equable temperature Xeroderma tends to improve to some extent at puberty only to get *worse again* with advancing age The worst cases remain severe in adult life

Diagnosis—This is usually easy Differentiation has sometimes to be made from acquired atrophy with scaling of the legs or from phrynoderma (*keratosis follicularis*) caused by vitamin A and C deficiency The history and the distribution of the dry but not inflamed skin usually enables the correct diagnosis to be made

Treatment—Warm baths may be taken daily followed by the rubbing in of a suitable ointment Individual preferences vary Some like to rub in soft paraffin ointment while the skin is still moist others prefer the ointment of wool alcohols or glycerin of starch with either hydrous lanolin or salicylic acid ointment in equal proportions A superfatted soap should be used but not to excess The administration of thyroid extract or of vitamin A is without effect

PIGMENTARY ANOMALIES

The colour of the skin depends on the amount of skin pigment (melanin) it contains on the thickness of the epidermis and on the amount and oxygen content of the blood flowing through the more superficial vessels of the dermis The muddy colour of acne is related to the relatively opaque thickened horny layer and increased sebum flow the patchy redness of rosacea to the static dilatation of the cutaneous vessels and the peachlike skin of the maiden to her naturally thin and smooth relatively translucent feminine horny layer overlying blood vessels neither statically dilated nor contracted but responding normally to changes of temperature and of mood The colour of the skin is a poor index of the hæmoglobin content of the blood If the blood vessels of the skin are dilated anæmia may be masked and if they are contracted there may be considerable pallor without anæmia

Pigmentary changes in the skin may be due to an excess or insufficiency of melanin or to the presence of extraneous substances including blood pigments bile pigments carotene mepacrine gold silver lead bismuth and various substances introduced in tattooing either by accident or intention

PHYSIOLOGY OF MELANIN FORMATION

Melanin a complex iron free substance is formed in the melanoblasts by the action of a ferment dopa oxidase on a colourless precursor dihydroxyphenyl alanine (dopa) dopa is formed from tyrosine by tyrosinase but only in the presence of copper Melanin synthesising cells (melanoblasts) can be differentiated from melanin containing cells (melanophores) by the dopa reaction fresh tissue is immersed in a solution of lævo rotatory 3 4 dopa when the melanoblasts are stained brown Reducing substances for example ascorbic acid inhibit melanin formation and oxidising agents stimulate it Dimercaprol (B A L) and thiouracil may inhibit pigment formation a may the monobenzyl ether of hydroquinone when applied locally

Melanoblasts are dendritic cells scattered amongst the germinal epidermal cells of the basal layer The melanin is carried by their dendritic processes to the cells of the basal and prickle layers and deposited as granules within them Pigment containing cells (melanophores) are also seen in the dermis they take up any melanin that passes from the epidermis to the dermis Increased melanotic pigmentation of the skin may occur with or without previous inflammation of the skin and may be general or local

INCREASED PIGMENTATION

Racial pigmentation affects the buccal mucosæ as well as the skin Without prior knowledge of the inheritance it is sometimes difficult to decide if pigmentation is racial but a consideration of the colour of the eyes and the colour and texture of the

hair together with other racial anatomical traits of facies etc usually prevents error

Physiological pigmentation—In pregnancy there is patchy facial pigmentation (*chloasma uterinum*) linea nigra in the midline of the abdomen and darkening of the nipples and genitalia, often as an early diagnostic feature

Congenital forms include pigmented, fleshy hairy moles, lentigines and ephelides or freckles The mongolian spot is a blue black discolouration of the skin often in the sacral region, and is a deeply situated mole In neurofibromatosis (von Recklinghausen's disease) there are pigmented patches on the skin which may precede the development of tumours by many years

Ephelides (*Freckles*)—These are pale brownish macules which become darker after exposure to sunlight They are seen particularly in sandy or red headed persons and those with ancestors of these colourings

Histologically the only change is an increase of pigmentation in the basal layer

Treatment is preventive by the wearing of broad brimmed hats and the use of sun screening creams Attempts at removal of freckles by peeling agents are hazardous and may result in dermatitis

Lentigines (*Non hairy Moles*)—A lentigo is a dark brown macule which does not change colour after exposure to sunlight

Histologically there is excessive pigmentation of the basal layer and an increase of clear cells The rete ridges are elongated and club shaped The basal cells may appear somewhat disorganised but the *epidermo dermal junction* is well defined Nævus cells are not present in the dermis

Course and Prognosis—Lentigines are seen in children but they become much more numerous after puberty and in pregnancy It is not uncommon for hundreds to be present on one person Lentigines are potential melanomata but malignant change occurs only in a very small proportion of them The stimulating factors appear to be the endocrine changes of puberty and pregnancy and physical traumata At certain sites malignant proliferation is much more common than at others These danger sites include the paronychial and subungual regions the soles the lower limbs more than the upper limbs and their distal parts more than their proximal parts clothing friction sites on the body and the face For this reason it is sometimes advisable prophylactically to excise lentigines on the soles or at friction sites before puberty or early in pregnancy For the rest treatment is not necessary but if for cosmetic reasons it is desired to remove a lentigo from the face it should be properly excised in full depth and not subjected to destructive cauterising or freezing procedures which may lead to activation of any cells that remain

Fleshy hairy moles—These are dealt with elsewhere (see Tumours)

Increased pigmentation from physical causes—The skin responds to light X irradiation heat and friction by increased pigment formation This may be seen as sun tanning and the effects of ultra violet baths pigmented macules are often present in the periphery of scars of lupus treated with the Finsen Lomholt lamp and prolonged solar irradiation leads to the condition of poikiloderma in which there are telangiectasia atrophy and macular pigmentation and depigmentation an identical condition to that occurring after excessive X irradiation A similar appearance also occurs in the rare congenital malady xeroderma pigmentosum in which there is an inborn susceptibility of the skin to light

Long continued exposure to tar or creosote causes pigmentation of the parts exposed to light the tar apparently being a light sensitiser Bergamot oil, too in creams or perfumery may cause pigmentation There may be mottled pigmentation of the face with some telangiectasia when creams are responsible or a necklace like line of pigmentation from beneath the ears around the neck when *Eau de Cologne* placed behind the ears has trickled down or been carried down in the sweat (berloque dermatitis) A similar pigmentation may occur after thorium X is applied to the skin

Certain plant juices have a photosensitising action (phytophoto dermatitis) par

ticularly wild parsnips figs the common rue and limes also convolvulus and agrimony and even the buttercup and bindweed A severe inflammatory reaction precedes the pigmentation

Heat may cause the condition known as erythema ab igne a network of pigmentation involving areas of skin corresponding to vascular anastomoses

Friction may cause pigmentation at truss hatband and other sites of clothing contact also in rubbed areas of itchy skin for example in pediculosis (vagabonds disease) prurigo lichen simplex etc

Certain dermatoses particularly lichen planus lichen simplex dermatitis herpetiformis and exfoliative dermatitis (erythroderma) are often accompanied or followed by much pigmentation In urticaria pigmentosa the pigmented macules urticate on friction Incontentia pigmenti is a peculiar reticular and mottled pigmentation of infants and is thought to be the end stage of an inflammatory process of unknown cause In pityriasis (tinea) versicolor the brown lesions are slightly scaly

Toxic pigmentation occurs from certain drugs for example arsenic which causes a raindrop effect of white spots in a dark background with skin coloured pinhead palmar and plantar keratoses and dirty grey keratoses more widespread on the trunk often leading to skin cancers Organic arsenic does not have this effect but may cause exfoliative dermatitis and secondary melanosis

Endocrine metabolic and nutritional disorders—In Addison s disease there is a diffuse pigmentation of the skin with involvement of the buccal mucosæ Pigmentation also develops *very often during treatment with corticotrophin* Diffuse pigmentation may occur in liver disease abdominal tuberculosis malignancy malaria diabetes and thyroid disorders In Gaucher s disease (kerasin lipoidosis) there is brownish discolouration of the skin In pellagra the skin is deeply pigmented on the parts exposed to sunlight particularly the backs of the hands probably from the absence of reducing substances which normally check excessive pigmentation on exposure to light There is also diarrhœa and dementia and often other evidence of malnutrition

Acanthosis nigricans (*q v*) presents as velvety skin piling up in folds particularly in the flexures

DIMINISHED PIGMENTATION

Racial differences in degree of pigmentation depend on varying physiological activities of the melanoblasts which are present in all races in approximately the same concentration

Albinism—In this condition there is a genetic lack of the enzyme tyrosinase a copper protein complex in which the copper plays an essential catalytic role

Vitiligo—*Vitiligo is the commonest form of depigmentation* There is a macular discoid and figurate depigmentation of the hands face genitalia or other regions On the scalp the hair may be white in the affected areas (leucotrichia)

Ætiology and Pathology—The ætiology is obscure Histologically melanoblasts are as numerous in the pale areas as in the darker surrounds but the melanoblasts in the pale areas are inactive (dopa negative) and they and the melanophores are deficient in pigment whereas those in the adjoining darker areas contain an excess

Diagnosis has to be made of this primary leucoderma from secondary leucodermas due to eczema psoriasis lupus erythematosus syphilis leprosy scleroderma or pityriasis versicolor

In eczematous or psoriatic leucoderma there is a history of a past inflammatory stage in vitiligo only of pale areas which redden but do not tan in sunlight In syphilitic leucoderma colli there are other manifestations of syphilis the lesions are uniformly small and confined to the neck and there may be some cutaneous atrophy which is absent in vitiligo

In leprosy the colour contrasts may not be so marked as in vitiligo, the pale areas are anæsthetic to light touch and differences of temperature, and thickened nerves can be felt serving the area or some other situation for example the neck the ulnar side of the elbow or the popliteal space When these nerves are rolled under the fingers the patient may experience paræsthesia but no pain in the area they supply The pale areas may be anidrotic

In scleroderma or its localised form morphœa there is increase of substance and marked hardening in the pale areas but no loss of sensation In scars and scarring diseases of the skin there is often depigmentation whether the scars are hypertrophic, normal or atrophic

In tinea versicolor the brown areas are "islands", the white areas the 'sea around In vitiligo the opposite applies the white areas being 'islands' in a 'sea of browner skin But the diagnostician has to be wary of certain exceptions to this rule Vitiligo may become so extensive that there is more pale skin than dark and in these circumstances brown areas may seem to represent 'islands' but if they do, their coastlines will be a series of bays or concavities indicative of the condition spreading from pale to darker zones In the form of vitiligo known as leucoderma centrifugum acquisitum (Sutton s disease) there is an intensely pigmented macule surrounded by a pale area beyond which is skin rather more brown than normal and beyond this normal skin

When skin affected with tinea versicolor is exposed to the sun the affected areas do not pigment as well as the normal skin around so that a photographic negative of the original malady is produced (*achromia parasitica*) In coloured people too, the affected skin of tinea versicolor is paler than the normal skin nearby The diagnosis is established in all doubtful cases by the more characteristic distribution of tinea versicolor on the trunk and by the discovery of spores and mycelial threads on scraping the lesions and direct microscopic examination of the material in potassium hydroxide

Leucoderma can arise from contact with rubber the responsible chemical being the monobenzylether of hydroquinone used as an antioxidant Clinically this type may be indistinguishable from the idiopathic form

Treatment—Meladine is said to bring about repigmentation It is the refined products of the plant *ammi majus linn* It is taken internally and applied on the surface the skin also being exposed to ultra violet rays Repigmentation begins around the hair follicles and it is probably only successful in those cases of vitiligo with pigmented hairs growing from the white skin such cases have melanoblasts in their hair papillæ which are still capable of responding to stimuli

NONMELANOTIC PIGMENTATIONS

Hæmochromatosis is a bronzed pigmentation which may involve the mouth there is diabetes and enlargement of the liver

Hæmosiderosis results from blood pigments which may be deposited in eczema and dermatitis involving the lower limbs in the capillaroses (Schamberg s progressive pigmentary dermatosis Majocci s purpura annularis telangiectodes lichenified and disciform pigmentary dermatosis of Gougerot and Blum angioma serpiginosum of Hutchinson)

The lemon yellow to brown pigmentation of jaundice is due to bile pigments in various concentrations Jaundice can be differentiated from racial pigmentation and other forms due to melanin by the involvement of the conjunctivæ the conjunctivæ are not tinted in mepacrine pigmentation when this drug is taken in therapeutic doses

Mepacrine pigmentation slowly develops with the daily ingestion of 0 1 to 0 3 g of the drug and the discolouration may take a month or two to fade after the drug is withdrawn The pigmentation of lichenoid mepacrine dermatitis is melanin

Carotinæmia due to the excessive ingestion of carrots produces an orange tint mo t marked on the palms The conjunctivæ remain white

Metallic intoxications—Lead causes a blue black line on the gums opposite areas of marginal gingivitis or caries owing to the deposition of lead sulphide Silver may if ingested or applied to the eyes or mucous surfaces be absorbed and cause localised or general argyria which gives a slaty blue colour to the skin due to local deposition of the metal A secondary melanoderma due to the irritating effects of the silver on the melanobla ts also may occur Gold may become deposited in the skin (auriasis) giving it a brownish colour or may if it causes a lichenoid or exfolia tive dermatitis result in much increase of melanin formation Bismuth may cause a black line on the gums but does not affect the skin except secondarily either gener ally by the rare occurrence of exfoliative dermatitis or locally when the injection is accidentally given too superficially and a white foreign body reaction occurs with ulceration through the skin which may persist for months and end in ugly scarring

TATTOOING

Tattooing may be accidental or intentional In the accidental form explosive materials coal dust or road surface materials are usually responsible In the inten tional form when tattooing has been used for identification purposes only one colour has been used but various pigments may be used when the purpose is display The blue black colour owes its bluish tint to the effects of the overlying dermis the pigment being some form of carbon iron oxide or logwood The colour red is due to cinnabar (mercuric sulphide) and is important because it may be the cause of allergic reactions and may also modify the development of a syphilitic dermatosis owing to the spirochæticidal effect of the mercury A green colour may be produced by chrome oxide hydrated sesquioxide or phthalocyanide dyes a yellow by ochre or by cadmium yellow but this has a bad reputation for causing blistering on sub sequent exposure to light

Tattooing has been responsible for inoculating syphilis tuberculosis vaccinia and virus hepatitis psoriasis and lichen planus may be set off in tattooed areas

Tattoos may be removed by excision with or without grafting or by various methods destructive to the dermis including carbon dioxide snow caustics and abrasives

PIGMENTED TUMOURS OF THE SKIN

These include moles melanomata Mongolian spots basal cell carcinomata keratoses juvenile and senile (seborrhœic) warts leiomyomata fibromata Darier s disease and acanthosis nigricans (*q v*)

VASOMOTOR DISORDERS

ERYTHEMA PERNIO (CHILBLAINS PERNIONES ERYTHROCYANOSIS ACROCYANOSIS)

A condition of bluish red cold skin of exposed parts with swelling and itching caused or aggravated by exposure to damp cold

Ætiology and Pathology—The chief cause is damp cold operating on a skin which is by inheritance oversensitive to its influence Arteriolar vascular spasm results with anoxæmia of the affected parts at first intermittent later chronic The blood stagnates in the statically dilated venules leading to œdema degeneration and fibrotic thickening of the connective tissue and of the vascular endothelium itself

Puberty is the time of worst involvement Insufficient exercise is an important factor (or paralysed muscles as in poliomyelitis) The outward application of heat *to the chilled surface aggravates the condition* Thromboses or extravasation of blood may occur, leading to ulceration

Clinical Picture —Perniosis may affect any area exposed to cold particularly the distal parts of the limbs the nose and the ears Involvement of the upper limbs is usually confined to the digits but on the lower limbs the calves are affected as often as the feet

Chilblains are far commoner in females than in males a fact only partly explained by their more scanty clothing The more sedentary tasks often carried out by women in cold draughty *or even damp surroundings are also partly responsible and it is* probable that some unexplained endocrine factor is of importance Chilblains present as bright pink or bluish swollen, non pitting areas of skin Blotchy redness is present at one area blueness at another The blue areas become red temporarily after gentle massage from the periphery Chilblains often itch severely and may feel warm to the finger in this red swollen stage but later when the vessels have become statically dilated as on the legs of young women (*erythrocyanosis crurum puellarum frigida*) the affected parts feel cold and are deep blue in colour except where casual contacts have emptied the superficial vessels Often the blue discoloration is most marked around the hair follicles If the œdematous process is marked bullæ may develop and on rupturing leave ulcerated chilblains Fissures (chaps) form on the fingers and hands and infection may lead to cellulitis

Course and Prognosis —Individual attacks resolve with the coming of more clement weather or with better precautions against damp cold, but each attack leaves the tissues less able to withstand cold in subsequent winters

Diagnosis —On the face and hands chilblains have to be differentiated from lupus erythematosus profundus (lupus pernio of Hutchinson) This may be extremely difficult except after a period of observation Lupus erythematosus persists in warm weather childblains do not

On the face and hands chilblains also have to be differentiated from sarcoidosis *(lupus pernio of Besnier) a persisting doughy bluish swelling of* the nose, ears or digits The histology will help if doubt exists on clinical grounds

On the legs perniosis has to be differentiated from Bazin s disease and from Darier Roussy subcutaneous sarcoids Both of these conditions occur in individuals with perniotic circulations but in addition there are extensive areas of hard bluish nodulation perhaps with deep and extensive ulceration

Erythema multiforme may cause lesions resembling chilblains on the fingers but the palms are also often affected and characteristic target *lesions may be seen*

Treatment —Once it is known that there is a tendency to chilblains every effort should be made to prevent aggravation by suitable warm clothing all over the body as well as to the affected part by proscribing the sudden application of heat to the affected part by attention to bad housing by draught elimination duck boarding on stone floors etc by adequate exercise and the avoidance of standing or sedentary jobs by warming the affected parts by exercise of the whole body or by the gradual and diffuse application of warmth with massage to help the venous *blood flow* An electric blanket is preferable to a hot water bottle

Drugs hold a minor place in the treatment of chilblains and it is important to make the patient realise that alleviation depends much more on the *correction* of faulty habits than on medicines Thyroid may be prescribed if there is any evidence of hypothyroidism A temporary increase in the blood flow to the extremities may be brought about by tablets of nicotinamide 50 mg or of tolazoline hydrochloride (Priscol) 25 mg Calcium has for long had a reputation for relieving *chilblains* by some means as yet unexplained it is best prescribed in tablet form with vitamin D_2 The use of massive doses of vitamin D_2 for the control of chilblains is

inadvisable in view of the possible serious side effects General ultra violet and infra red irradiation may help

For unbroken chilblains calamine liniment may be rubbed in from the periphery For fissures the ointment of wool alcohols is comforting Appropriate antibiotics may be required to control secondary infections

ROSACEA (ACNE ROSACEA)

This condition is primarily erythematous and secondarily papular it is characterised by lability of the facial blood vessels going on to persistent static dilatation and to congestive hypertrophy and inflammation of the pilosebaceous follicles sometimes ending in necrosis

Ætiology and Pathology—Rosacea is essentially a state of vasolability of the face particularly the centre of the forehead the nose the fronts of the cheeks and the chin The vessels respond excessively to emotional stimuli to changes of temperature and to gastric irritants The gastric vessels and musculature tend to be hypotonic but there is no uniform change in gastric secretion as shown by test meals Hormonal (menopausal) influences are sometimes important

The rosaceous patient is characteristically obsessional with very high standards of conduct and much resultant anxiety if these standards are not maintained Excessive (often self imposed) activities and insufficient time for meals result in a sense of hurry flatulent dyspepsia and flushing of the face Anger if habitually repressed may also cause flushing of the face as may feelings of shame or embarrassment A seasonal exacerbation in the early spring is sometimes noted

Histologically there is vascular dilatation and focal inflammatory nodules either of lymphocytes or of tuberculoid type with lymphocytes epithelioid cells and giant cells There may be some perifolliculitis and abscess formation and all degrees of hyperplasia of the sebaceous glands from a moderate degree in papular rosacea to an extreme degree in rhinophyma In the latter condition there is also fibrous hyperplasia

Clinical Picture—The patient is usually a woman aged between 30 and 50 but men also are often affected and adolescents of either sex may suffer from this malady The patient complains of redness and pimpling of the face with aggravation from exposure to extremes of temperature from hurry anger embarrassment or general anxiety from hot drinks or indigestible foods or in the premenstrual tension phase There may be a flatulent dyspepsia At first there is only a tendency to flush or blush easily later the redness becomes persistent telangiectases being visible and finally red pimples form which may suppurate or necrose giving rise to crusted papules which end in depressed scars There are no comedones but sometimes acne vulgaris coexists more commonly acne at puberty is succeeded by rosacea some years later Patients with rosacea usually show evidence of the seborrhœic state with all its consequences Conjunctivitis blepharitis keratitis and corneal ulceration may all complicate rosacea

Rhinophyma is a rare disorder and much more common in men than in women Irregular fleshy masses develop on the distal two thirds of the nose with visibly enlarged follicular orifices

Course and Prognosis—Rosacea is amenable to treatment provided the patient is willing and able to co operate with the physician A variable amount of scarring may be left The eye lesions may cause serious impairment of vision

Diagnosis is from acne vulgaris lupus erythematosus contact eczematous dermatitis and polycythæmia In acne vulgaris the distribution is different the face is muddy not red and comedones are present In the rosaceous form of lupus erythematosus atrophy can be discerned and the eruption is worsened by exposure to the

sun Contact eczematous dermatitis may coexist It presents with ill defined areas of redness and peeling at various sites on the face, particularly the eyelids around the mouth and on the neck In polycythæmia the whole face is persistently plum coloured

Treatment—All circumstances that are likely to bring about flushing of the face have to be avoided Exposure to cold winds, fires or for that matter the kitchen stove have to be avoided as far as possible Hot drinks too are harmful particularly excessive hot tea drinking and they are a more common cause of exacerbation than alcohol, condiments or indigestible food Obsessional traits have to be moderated if possible Adequate time must be allowed for meals which should have ample protein and vitamin content with no excess of fats or carbohydrates The patient must be encouraged to express hostility more naturally More fundamental psycho logical factors are on the whole, best left undisturbed because the patient with rosacea usually cannot tolerate this line of approach

Rosacea is not related to nutritional deficiency except secondarily through the associated gastric disturbance Vitamin B complex and iron are sometimes indicated, and it is always wise to estimate the hæmoglobin content of the blood Internal treatment also consists of sedation gastric ' tonics ' and when necessary œstrogens A useful medicine before meals is sodium phenobarbitone gr ½ in either the acid or the alkaline gentian mixture Sometimes an acid mixture seems to be more helpful sometimes an alkaline one Fractional test meals show marked variations from one rosaceous patient to another and for that matter, in the same patient on different occasions hence they are of little value in deciding on the best medication Bromides and iodides should not be given to rosaceous individuals as they may grossly aggravate the condition

Œstrogens are sometimes indicated for example ethinyl œstradiol 0 05 mg twice a day for 10 days preceding each monthly flow, or the same remedy may be given once daily for up to 3 months to post menopausal women

Local treatment is relatively a secondary matter Zinc sulphate lotion or calamine lotion with 1 per cent of sulphur or of ichthammol, may be used The patient must not wash the face in very hot or very cold water and should not manipulate the lesions Occasionally the lesions become infected, and then need treatment with the appropriate antibiotic

In patients with sebaceous hypertrophic nodules X ray exposures 150 r weekly on up to four occasions may help

In rhinophyma the large masses may be reduced by X ray exposures of 250 r each up to a total of 1000 r but surgery is better the lesions being pared down with a scalpel or razor under general anæsthesia until the normal contour of the nose has been regained bleeding being controlled with the galvano cautery

For the conjunctivitis the zinc and boric eye lotion is useful Keratitis needs the attention of an ophthalmologist Bright light must be avoided Homatropine drops are indicated and cortisone drops give great relief

RAYNAUD S PHENOMENON

This is described on p 922 It may occur with perniosis lupus erythematosus or scleroderma

ERYTHROMELALGIA

This is a persistent painful warm redness of the extremities It is dealt with elsewhere (see p 924)

DERMATITIS DUE TO PHYSICAL CAUSES

Dermatitis may be caused by heat or cold maceration or drying ultra violet irradiation X rays thorium X or radium and by mechanical causes including friction and pressure

DERMATITIS DUE TO HEAT

ACUTE HEAT EFFECTS —These are those caused by dry heat (burns) and moist heat (scalds) and are dealt with at length in surgical textbooks Suffice it here to say that a first degree burn (erythema only) arises when the heat causes drying of the surface but insufficient damage to lead to exudation into the skin The treat ment consists of the application of a bland animal fat such as lanolin preferably mixed with mineral oils as in the ointment of wool alcohols

In a second degree burn there is erythema and blistering with a risk of infection once the blisters are broken and of loss of protein and electrolytes if the blistered area is extensive Intact blisters should be punctured under aseptic conditions allowed to collapse and then covered with a gauze dressing The roofs of ruptured blisters should be cut away and the raw area swabbed with a 1 per cent solution of cetrimide in a sweeping centrifugal action Tulle gras dressings enable healing to proceed with the minimum of trauma to the young granulation tissue

The treatment of third degree burns is a surgical matter

ELECTRIC BURNS —Electric burns are often painless aseptic and dry but slow in healing The treatment is similar to that of other burns

CHRONIC OR RECURRENT HEAT EFFECTS —This causes the condition known as erythema ab igne often seen on the legs of women There is a pigmentary network corresponding with the sites of anastomoses between adjoining venous areas

CLIMATIC HEAT EFFECTS —Miliaria rubra (prickly heat) (See Anidrosis)

DERMATITIS DUE TO COLD

PRURIGO HIEMALIS —An itching eruption occurring only in the winter usually confined to the legs sometimes affecting the forearms and thighs Changes of temperature for example undressing hot baths sitting near fires precipitate the itchy episodes The lesions are inconspicuous patchy mild lichenification and scratch marks and marked dryness of the skin

Treatment consists of the avoidance of extremes of temperature and of the excessive use of soap Calamine liniment is helpful

LIVEDO RETICULARIS —This is a condition in which the legs show a livid network of venules the network corresponding to the anastomoses between the adjoining venous areas

CHILBLAINS —A chilblain is a static dilatation of venules secondary to anoxia caused by arteriolar spasm (see Vasomotor Disorders)

IMMERSION FOOT (TRENCH FOOT) —This is due to prolonged exposure to cold water insufficient to cause frostbite The feet are white red or cyanotic The patient complains of numbness and cramp Minor injuries may cause gangrene On removal from the cold a red swollen blistery hyperæmic stage develops unless the parts are very slowly warmed

Treatment is by gradual warming cleansing and elevation of the limb followed by exercise and the application of salicylic acid dusting powder

FROSTBITE (DERMATITIS CONGELATIONIS) —This is due to freezing of the soft tissues with cessation of the blood flow On thawing there is an erythematous a bullous or a gangrenous reaction

Treatment is by very gradual defrosting and treatment of the damaged tissue on recognised surgical lines

DERMATITIS DUE TO ACTINIC RAYS

ACUTE SOLAR DERMATITIS —This arises from excessive exposure to the sun and may occur in all degrees of intensity as with heat burns It is treated on similar lines

CHRONIC SOLAR DERMATITIS —Repeated exposures to the sun cause premature changes of ageing in the skin The physical signs consist of atrophy with telangiectasia pigmentation and depigmentation and a tendency to form keratoses It is *sometimes called 'farmers' skin' or 'sailors skin'* and is seen on the face and on the backs of the hands, rarely also on bald heads Another condition sometimes known as 'peasants skin , occurs on the back of the neck in the form of lozenge shaped pink thickened areas of skin (see Dermatitis rhomboidalis nuchæ)

ECZEMA AB SOLARE —This condition of hypersensitivity to light may present in many forms hence the term 'polymorphic light eruption The same individual in one attack may show eczematous features and in another pruriginous ones The lesions are on the forehead, cheeks ears and exposed parts of the neck and limbs Many substances applied to the skin have a light sensitising effect These include tar bergamot oil, acriflavine sulphonamides and eosin Dermatitis bullosa striata pratensis is a bullous dermatitis of exposed parts coming on after contact with a light sensitising plant followed by exposure to the sun (phytophoto dermatitis) Various plant juices including lime, figs rue wild parsnips, etc, may have this effect Some drugs also have light sensitising effects particularly sulphonamides and other drugs having hepatotoxic properties

PRURIGO ÆSTIVALE —This occurs in children and is a papulo erythematous rash on the exposed parts which recurs only in summer months

HYDROA ÆSTIVALE VEL VACCINIFORME (HUTCHINSON S SUMMER PRURIGO) —This severe bullous eruption of the exposed parts recurs each summer most commonly in boys and is associated with congenital hæmatoporphyria It results in pock like scarring

XERODERMA PIGMENTOSUM —In this rare malady there is an inborn over sensitivity to ultra violet and visible rays and, as a result senile atrophic changes resembling radiodermatitis develop at an early age and the sufferer may in adolescence begin to develop keratoses and skin cancers on the face backs of the hands or on the legs

Treatment —The skin can be protected from ultra violet irradiation by a cream containing 15 per cent of para aminobenzoic acid, 10 per cent salol or 5 per cent tannic acid in hydrous ointment or a particulate screen against ultra violet and visible rays can be provided by the compound paste of titanium dioxide Oily calamine liniment is necessary to soothe any severe reaction

DERMATITIS DUE TO RADIOACTIVITY

X rays and radium may cause acute changes in the skin, from one large exposure or several or chronic changes from repeated small exposures

ACUTE EFFECTS —Kienbock classified X ray burns as

First degree latent period 3 weeks no visible inflammation temporary shedding of hair

Second degree latent period 2 weeks redness and swelling of the skin lasting 1 to 2 weeks, falling of the hair

Third degree latent period 10 days redness superficial erosion and vesiculation parts restored to normal in 3 to 4 weeks

Fourth degree latent period under a week necrosis with ulceration healing takes 6 weeks or longer

Treatment of X ray burns is similar to that of other burns

CHRONIC EFFECTS —These are similar to those of repeated and long continued over exposure to the sun There is atrophic scarring with pigmentation depigmentation and telangiectasia Keratoses develop and squamous carcinoma may be the final result

DERMATITIS DUE TO MECHANICAL CAUSES

Continuous pressure on the skin tends to cause pigmentation and atrophy

Intermittent pressure causes corns and callosities

The acute effects of friction include blistering and epidermolysis bullosa the more chronic ones lichenification and hyperkeratosis

Excessive wetting of the skin causes the epidermis to become sodden and prone to fungous and coccal infection Excessive dryness of the atrophic skin causes a condition resembling a dried out mud bank with irregular or rounded areas peeling at their margins and with shallow fissures between them (eczema craquele) or deep fissures perhaps with secondary infection

DERMATITIS ARTIFACTA

Hysterical personalities sometimes produce blisters and sores on the skin by physical or chemical means and in so doing gain the sympathy freedom from work and (sometimes) pecuniary gain that they so much desire Of these motives the desire for attention loving care and sympathy is the strongest The lesions may be produced by sharp instruments friction constricting bandages hot coins cigarette ends caustic liquids and in various other ways

Clinical Picture —The patient is usually a young woman Usually there is a trivial wound or burn which does not heal as soon as might be expected on the contrary it extends with blistering or sloughing ulceration The lesions are bizarre discoid or linear sometimes with straight edges Hot coins cause round blisters cigarette ends cause small sloughing ulcers and caustic liquids cause linear discolourations dermatitis or sloughing often with a gravitational trickle where the caustic has flowed over the surface The lesions are always at sites easily reached by the right hand in right handed persons and at sites easily reached by the left hand in left handed persons the face breasts forearms and hands are favourite sites

The patient shows the belle indifference of the hysteric and examination reveals Charcot s triad of anæsthesia of the cornea and pharynx with suggestion anæsthesia of the skin perhaps in glove and stocking distribution

Hysteria cutis is also seen in other guises When compensation claims remain unsettled occupational dermatitis may continue as lichenified dermatitis long after the patient has been removed from the irritant This occurs particularly at the bends of the elbows in what may be called maintained dermatitis

In several other skin reactions particularly pompholyx eczematous dermatoses pruritus vulvæ infective dermatitis and psoriasis the persistence of the dermatosis or its exacerbation often seems to serve the purpose of enabling the patient to avoid some repugnant task or action and to receive care and attention The psychodermatological mechanisms of these conditions has not yet been explained

Treatment of all these hysterical reactions is extremely difficult It is one thing to understand the psychological mechanism but quite another to help the patient towards a better and more positive attitude to life It is useless to accuse the patient it will be indignantly denied A reasonable level of self esteem must be maintained Often the physician has to be satisfied with relief of the current manifestation by a modicum of sympathetic care and occlusive dressings knowing very well that the hysterical personality persists and will continue to react in this fashion to sundry future life situations Care should be given to finding suitable occupation, when work shyness is a factor The home conditions should be investigated and an attempt made to modify any unsuitable attitude of relations

DERMATITIS DUE TO CHEMICAL SUBSTANCES

Chemical substances may come into contact with the skin in gaseous liquid particulate or solid form and in so doing may cause dermatitis Two types of contact dermatitis are recognised

(1) DERMATITIS DUE TO PRIMARY IRRITANTS —These are substances that cause dermatitis in everyone if they are applied to the skin in sufficient concentration and for sufficient time They cause physio chemical alterations in the structure of the skin and act in various ways mechanical physical or chemical They may abrade the surface destroy keratin, abstract fat or mix with skin fat macerate or desiccate precipitate protein, oxidise or reduce hydrolyse form toxic nitro derivatives or stimulate keratin formation Primary irritants include inorganic acids and alkalis certain inorganic elements and salts organic acids solvents, essential oils certain dyes and tar and petroleum products

(2) DERMATITIS DUE TO SENSITISERS —These are substances which provoke dermatitis only in a few hypersensitive persons They consist mainly of complex organic chemicals, certain vegetable and animal products and a few inorganic chemicals which are able to take on sensitising properties when they are combined with protein They include plants dyes developers rubber accelerators and antioxidants soaps insecticides cosmetics oils, resins coal tar derivatives and explosives Certain chemicals and plants have a photo sensitising effect on the skin for example tar eosin, acriflavine sulphonamides and various plants including wild parsnips figs rue and many others Some substances can act both as primary irritants and as sensitisers For example soap has a primary irritant effect from its alkalinity and may have sensitising potentialities from the fatty acid part of its molecule Traces of chromium in cement may be responsible for sensitisation dermatitis from contact with this substance Bacteria fungi and parasites may cause or complicate occupational dermatitis

Ætiology and Pathology —*Predisposing causes of dermatitis* —Race complexion sex and age all modify the tendency to dermatitis White races are on the whole, more susceptible than dark races and blondes more than brunettes Women are more susceptible than men and children and the aged are more susceptible than young or middle aged adults But there are exceptions to these generalisations Sweating may leach out irritants from solids touched hairiness may carry with it some follicular vulnerability and although a greasy skin enables a person better to withstand contact with degreasing agents it also may expose him to greater peril from irritants that are miscible with skin fat Seasonal effects of sweating in the summer and chapping in the winter may be important An inherited susceptibility lack of cleanliness or reckless methods of cleaning up after work fatigue emotional instability or an anxious obsessional temperament and malnutrition may all play a part

Precipitating causes —The primary irritants most commonly responsible include soda and alkaline soaps cement and lime paraffin oil, petrol, diesel oil and turpentine

or turpentine substitutes lubricating cooling and cutting oils glue formalin phenol ultra violet or X irradiation or friction from gritty particles The sensitisers are many and include medicaments such as sulphonamides benzocaine penicillin flavine streptomycin formalin Lysol Dettol and adhesive dressings plants particularly Primula obconica chrysanthemums and many others teak ebony and other woods cosmetics including paraphenylenediamine hair dye eosin in lipsticks nail varnish bergamot oil and orris root powder clothes and jewellery including dyed furs wool and rubber chromium and nickel plating occupational hazards involving work with mercury chromium or nickel dyes and explosives flour improvers rubber antioxidants and very many others Occupations with more than average dermatitis *hazards include bakers carpenters cleaners dentists doctors dustmen dyers florists* french polishers garage hands gardeners housewives labourers machine hands miners nurses painters photographers platers rubber workers and tar workers

The development of dermatitis from primary irritants depends *inter alia* on the possession of skin secretions with poor alkali neutralising properties on some degree of xeroderma with insufficient sebum production to replace that removed by fat solvents and emulsifiers and on thinness of the horny layer

The cause of eczematous eruptions is the sensitisation of the epidermal cells to a continuously or repeatedly encountered agent It is possible that a heightened excitability of the nervous system as a whole (of which the skin is an end organ) is one important factor Sufferers from eczematous eruptions often show emotional lability which is more marked during exacerbations of the dermatosis and outbreaks may coincide with events causing emotional conflict

The mechanism of spread of eczematous sensitisation is far from settled There is some evidence that the lymphocytes convey antibodies to remote areas of the skin The manner of spread of eczematous processes also suggests nerve transmission as being partly responsible Sensitisation often spreads at first locally and then to a similar site on the opposite limb and to the comparable situation on the other two limbs before becoming generalised Examples of this include eczema of one leg spreading to the other and then to the forearms and ringworm of the feet with its manual mycide eruption

The incubation period from the first application of a substance to the development of sensitisation is variable and often indeterminable Flavine and sulphonamides may sensitise after 4 days penicillin after 8 to 10 days and some other substances after a longer interval Traumatic breaks in the continuity of the surface of the epidermis are most important The prickle cells of the Malpighian layer are normally protected from external noxæ by an intact horny layer and they react violently if they are exposed to primary irritants or to sensitising substances

In the acute stage there is spongiosis (intercellular and intracellular œdema) in the prickle cell layer causing microscopic or macroscopic vesicles and a variable degree of disintegration of the epidermis In the dermis a lymphocytic infiltrate surrounds the dilated vessels the sweat glands and the pilosebaceous follicles In the subacute and chronic forms there is parakeratosis (nucleated horn cells) acanthosis and a chronic inflammatory infiltrate in the dermis

The histopathology of dermatitis due to primary irritants differs from that of sensitisation dermatitis in that the infiltrate is more polymorphonuclear in the former and lymphocytic in the latter

Clinical Picture—In the most acute forms due to caustics there is destruction of the epidermis before an inflammatory reaction can develop In less acute forms there is smarting redness and swelling going on to vesiculation and blistering and a raw surface In subacute forms there is papulo vesiculation with abnormal scaling Milder and chronic forms present as redness and pathological scaling with lichenification increase of pigmentation and a tendency to fissuring

The reaction usually remains localised to the site of contact, sometimes with an

overlap of up to 0 5 cm apparently from a local reflex but if the irritant or sensitiser is in liquid or semisolid form, as often applies with contact medicaments the dermatitis tends to spread up to and just beyond the limits of each application If the irritant or sensitiser is miscible with sebum, the reaction may be mainly follicular and discrete follicular papules may develop beyond the zone of confluent dermatitis

Dermatitis varies in appearance according to the stage at which it is seen Erythema papulation or vesiculation predominate in the earlier stages later according to the degree of secondary infection or of rubbing and scratching it may go on to pustulation with moist infected scabs on an exuding surface or to lichenification and blood scabbing If neither complication develops resolution follows on the moist exuding surface by serous scabbing decreasingly coarse scaling diminution of redness and a return to the original state If at any stage a further contact with the causal agent takes place the whole process may recur

Course and Prognosis—This depends on the discovery of the cause and the possibilities of its subsequent avoidance Sometimes a trade irritant can be replaced by something harmless sometimes a process can be modified so as to lessen the exposure of the workman, sometimes protective clothing better ventilation and washing facilities are all that are needed 'Hardening by continuous re exposure is not likely to be successful With some specific sensitisers (for example streptomycin) desensitisation can be carried out, with others there may be a group sensitivity to chemically similar substances (for example sulphonamides flavine benzocaine paraphenylenediamine) or there may be a nonspecific broadening of sensitivity to many substances probably accompanied by increased emotional lability In this last form the prognosis is poor the causes often being undiscoverable

Diagnosis of primary irritant and sensitisation dermatitis on the face has to be made from solar dermatitis facial prurigo urticaria infective dermatitis and erysipelas on the body from ringworm seborrhœic dermatitis pityriasis rosea lichen planus psoriasis and parapsoriasis on the hands from nummular eczema mycides erythema multiforme and psychogenic pompholyx

Solar dermatitis affects the forehead and malar ridges contact dermatitis more characteristically affects the eyelids lips and neck, facial prurigo is accompanied by hay fever, asthma or flexural dermatitis urticaria is not accompanied by peeling erysipelas has a brawny spreading edge and there are constitutional symptoms on the body the other diseases and reactions are usually more circumscribed, on the hands nummular eczema affects the backs but adjoining areas escape entirely whereas with dermatitis the clefts are more typically affected and the eruption is more diffuse Psychogenic pompholyx is symmetrical whereas eczematous dermatitis of the hands may be asymmetrical At all sites frictional dermatoses (lichenification) have to be differentiated from spontaneous eruptions (eczema dermatitis)

The label contact (eczematous) dermatitis ' having been affixed on the basis of the morphology of the lesions the physician s more difficult task is to find the cause For this purpose it is necessary to know the ways in which sensitising substances may come in contact with the skin and the likelier causes of eczematous dermatoses affecting various parts of the body The problem is easier in dermatitis produced by primary irritants than when sensitisers are responsible The history is all important with possible seasonal fluctuations relief at week ends or on holiday and other significant evidence that the patient alone can supply Leading questions are necessary to uncover possible occupational causes including hobbies hygienic practices clothing cosmetics jewellery plants and other volatile agents day by day contacts and past treatments Sometimes the history can be supplemented by a diary of daily contacts kept by the patient after which patch tests can be performed with suspected sensitisers The distribution suggests the likely causes

On the scalp the likely causes include paraphenylenediamine hair dye permanent

waving solutions brilliantine and perfumes hair lacquers hat bands and occasionally medicaments On the face air borne and inadvertently hand transferred substances have to be considered also topical medicaments and cosmetics The eyelids are particularly affected by vapours and plant pollens thus formalin vapour primulæ chrysanthemums streptomycin are common causes as are also eye lotions drops and ointments and occasionally nail varnish and other hand transferred agents On the neck hair dyes fur collars and other dyed materials are suspect, also hand transferred irritants and dusts having a primary irritant action such as lime or cement Dusts also affect sites of pressure from clothing and within the socks as well as the hands Clothing when occasionally it is causal tends to affect the neck the axillary folds the belt line the buttocks hips and perineum the sock areas and the dorsa of the feet Nickel plated fittings and jewellery may affect many sites, including the neck lobes of ears mid line of back wrists and thighs

The pattern of contact dermatoses on the hands depends on the physical nature of the contactant solid particulate or liquid as well as on its chemical properties Liquids tend to affect the fronts of the wrists and the clefts of the fingers, powders have a more diffuse action inserting the hand into containers of powders or liquids may cause an eruption on the back of the hand and objects handled may occasionally cause eruptions at various sites depending on the type of grip

The accurate recognition of sensitisers depends to some extent on patch tests These are helpful if the results are interpreted correctly For success there should be adequate control suitable concentrations of the suspected sensitisers no patch testing with primary irritants inspection at 48 hours and reinspection at 3 to 5 days Contact eczematous responses (erythemato vesicular) must be differentiated from follicular obstructive effects (folliculo papulo pustular) and noted at the time of removal and from the trauma of removal of the adjoining adhesive (erythemato-folliculo papular occurring within a few minutes of removal) The conditions of patch testing and those in which the sensitiser is met in everyday life can never be identical (site sweating abrasions fissures friction etc) and allowance has to be made for this A positive patch test does not of necessity prove that the dermatosis was produced by this substance and a negative patch test does not completely rule out that the tested substance has been the cause of the original dermatitis Patch tests are best performed on the back of the chest The patient should not know which patch is which but suitable identification marks should be made on the adhesive dressings Patch testing should not be performed in the presence of active dermatitis and if the dermatitis has been severe patch testing should only be performed after complete clearance and with expert supervision the patient being instructed to remove the patches at once if a severe reaction occurs If this is not done an acute relapse may result at the sites of the original eruption

Treatment—This consists of prevention desensitisation when possible and symptomatic treatment

The essentials in the prevention of occupational dermatitis are selection of the most suitable workers their protection at work their periodic inspection and supervision to see that precautionary measures are conscientiously carried out and the provision of adequate washing facilities Selection includes rejection of hyperidrotic seborrhœic or xerodermatous individuals or those with prurigo tinea pedis or acne vulgaris as far as certain trade procedures are concerned Protection includes good ventilation abatement of humidity exhaust draughts suitable clothing and goggles and barrier creams which may have either water repellent or oil repellent effects and also emollient properties Inspection covers not only the working conditions and the proper use of protective appliances but also medical inspection of the workers for minor injuries and infections that may be the precursors of something more serious Washing facilities must be adequate and the worker must be discouraged from using paraffin petrol, scouring agents and other primary irritants for cleaning

the skin In some industries these are the cause of more sickness than the industrial hazards themselves

Desensitisation can occasionally be performed for example, in streptomycin cutaneous sensitivity by graduated intradermal injections This procedure is most valuable when the sensitivity interferes with a person's skilled occupation, but if the work is unskilled and there are opportunities for alternative employment it is better to remove the patient from the irritant than to attempt desensitisation, furthermore, hypersensitivity is often nonspecific and multiple sometimes only to similar chemical substances such as sulphonamides but in others to dissimilar substances and even to physical agents such as light

Attempts at hardening' by continuing to expose the worker to an occupational sensitiser are more likely to bring about ever increasing sensitivity, ending in generalised eczema than to succeed in enabling him to continue in the work

Local treatment in the acute phase consists of applications of oily calamine lotion with light dressings of butter muslin (which gets less entangled in the scales and crusts than does surgical gauze) held in place by cotton bandages The dressings are changed only once a day a bland vegetable oil or liquid paraffin being used gently to remove debris from the surface of the skin before another application of lotion is made For any infection that may develop soaks in 1 in 6000 solution of potassium permanganate are helpful, with applications of the appropriate antibiotic, depending on the cultural findings

As the condition gets less acute zinc or calamine cream or hydrous ointment may be used and when the eruption becomes scaly Lassar s paste or the ointment of wool alcohols are more useful Finally, if lichenification is tending to develop a 2 per cent tar paste makes a useful antipruritic application It is most unwise to use tar in the earlier stages and its use should be abandoned at once if there seems to be any tendency to the development of folliculitis At no stage should benzocaine anæsthetising substances be used in local applications as they have a great tendency in themselves to cause eczematous dermatitis Similarly, antihistamines are best avoided because eczematous dermatitis develops in about 3 per cent of cases in which they are used X-irradiation in fractional exposures is valuable in the chronic phase if the eruption persists in spite of nonexposure to the irritant

General treatment consists of rest to the body as a whole in widespread cases and to the affected part in local cases Sunlight heat and cold should be avoided Ample sedation to relieve the pruritus should be given In generalised cases due to sulphonamides flavine and other hepatotoxic substances the course may be shortened by intramuscular injections of a crude liver extract 4 ml daily

INFECTIVE (SEBORRHŒIC) DERMATITIS

This is one of the commonest and most important of skin diseases The term applies to many dermatoses differing in situation and pattern but in all of which there is a qualitative abnormality of the sebum The patient s skin is unduly susceptible to bacterial and fungous infection chemical and physical injury and emotional stress

Ætiology and Pathology—The triad of organisms found in seborrhœic dermatoses are the pityrosporon of Malassez (bottle bacillus) the acne bacillus and the *Staphylococcus saprophyticus* The organisms do not fulfil Koch s postulates in their relationship to seborrhœic conditions and they must be regarded as secondary invaders of the abnormal sebum follicles and horny layer

Histologically there is parakeratosis, hyperkeratosis and spongiosis (intra and intercellular œdema of the prickle cell layer) In the dermis, there is a lymphocytic infiltrate of moderate degree, with dilatation of the vessels

The seborrhœic individual is often obese and may indulge in fats and carbo hydrates to excess while taking insufficient exercise The diet is often deficient in foods containing protein and vitamins Drugs taken internally (for example sulphona mides) and various chemicals applied externally (for example flavine sulphonamides penicillin antihistamines and some occupational irritants) may provoke an infective outburst and emotional disturbances causing fear and loss of self esteem may have a similar effect

Clinical Types —There are three grades of intensity in infective dermatitis In the first and mildest there is a fine grey dry scaling showing on the scalp as dandruff or scurf (pityriasis simplex, seborrhœa sicca) without reddening of the underlying skin

In the second grade the scales are coarser and look and feel greasy (pityriasis steatoides) (This is due to a cellular infiltrate amongst the cells their fat content is not increased) The lesions may be solitary and pinhead sized grouped or con fluent and are found particularly where pilosebaceous follicles are most abundant

In the third grade there are moist red shiny exuding areas of skin with a sero purulent exudate and frank follicular pustules around The flexures are particularly affected and the horny layer of the opposing surfaces gets partly rubbed off and with the white sodden portions of epidermis remaining around a red shiny centre zone, gives the picture of intertriginous dermatitis Greasy crusts of seborrhœic impetigo may occur on the face and elsewhere Pyogenic staphylococci or hæmolytic strepto cocci may be found on culture or there may be a mixed infection with Gram-positive cocci and Gram negative fæcal contaminants

The sites commonly affected by infective dermatitis either alone or in combina tion are the scalp brows lashes eyelids conjunctivæ inner and outer canthi naso labial folds the vestibule of the nose postauricular folds over ears aural meati vermilion surface of lips angles of the mouth beard sweat grooves of centre of trunk submammary region axillæ navel pubis glans penis and coronal sulcus vulva genitocrural folds intergluteal cleft toe clefts and in discoid form on hairy areas of arms forearms thighs and legs as well as on the trunk

The possibility of an underlying infective dermatitis has to be considered in many cases of contact dermatitis and the converse also applies the diagnosis of infective dermatitis should not be made lightly without giving much thought to a possible contact cause for the attack

On the scalp there may be simple scurf (pityriasis simplex) on skin of normal colour or there may be profuse and widespread greasy scaling (pityriasis steatoides) on a reddened itchy skin the condition often extending a little on to the forehead as the corona seborrhœica The hair tends to fall more rapidly When the scalp becomes further infected with pathogenic cocci a condition of golden crusted and purulent seborrhœic impetigo arises

On the ears there may be a scaly and inflammatory condition of the meati perhaps with exudation or with folliculitis and perifolliculitis of the ceruminous glands giving rise to much pain and to varying degrees of meatal stenosis and deafness (meatitis) or the skin of the external ears may be inflamed (otitis externa) and scaling or exuding Above behind and beneath the ears the inflamed skin is very liable to crack and the painful fissures may form a portal of entry for streptococci causing streptococcal dermatitis or cellulitis (erysipelas) The ears are often contaminated with Gram negative fæcal organisms as well as with pathogenic cocci

The eyes may be affected in various ways—folliculitis of the brows or of the lashes (blepharitis) or styes inflammation of the skin and folds of the upper lids con junctivitis with chemosis and a slight sticky discharge or scaling and fissuring of the outer canthi.

The nose may have greasy scales and follicular plugs on the nostrils and at the nasolabial folds There may be a vestibular folliculitis

The vermilion surfaces of *the lips*, particularly the lower may show scaling and a tendency to crack (cheilitis exfoliativa) and angular stomatitis with fissuring is common

The beard area may be affected with a frank folliculitis (seborrhoeic sycosis) or there may be patchy or diffuse redness and exudate or scaling Occasionally impetigo is superimposed "Seborrhoeic" individuals are very susceptible to the haphazard and uncontrolled use of antibiotics and antiseptics on the skin, this is partly because they are very liable to become sensitised to topical agents, either the active component or the vehicle and partly because the use of antibiotics without previous culture and antibiotic sensitivity testing of the organisms grown often means that an unsuitable antibiotic is applied, with the result that the causal organisms thrive perhaps even being helped by the removal of competitors relatively harmless to the host

On the trunk, pityriasis simplex and steatoides are common in the mid line 'sweat grooves' In the obese intertriginous dermatitis may occur in all grades of severity in the axillary domes, under the breasts at the navel in the genitocrural folds and between the buttocks even under pendulous abdominal folds of fat Satellite follicular papulo pustules are grouped around the main lesions The coronal sulcus may be inflamed and balanitis supervenes (infective balano posthitis) *Folliculitis of the pubis* in varying degrees of intensity is present in the most intractable forms of this malady

Discoid or petaloid lesions of infective dermatitis may occur on the trunk and on the limbs particularly across the scapular region and on the extensor aspects of the limbs, even involving the backs of the hands or feet These lesions may be scaly sharply demarcated discs and ovals with a few discrete guttate papular lesions or in the more acute form there may be eczematous papulo vesicular discs going on to exudation and crusting (seborrhoeic, nummular or discoid eczema staphylococcide)

Intertriginous dermatitis between the toes makes an ideal medium for the growth of monilia and is a commoner cause of "foot rot than is pathogenic fungous infection in this region

In addition to all these patterns of infective dermatitis there are "seborrhoeides or 'eczematides conditions in which the use of one or other of various topical remedies sets off an explosive outburst of a papulo vesicular nature at first near the site of application later contralaterally and, finally in widespread fashion This condition is thought to be due to the development of sensitisation to bacterial or fungous products or the patient s own disintegrating epidermal cells or to the topical agent used (see autolytic eczema) It only occurs when there is profuse exudate or maceration at the primary site affected

Course and Prognosis are uncertain, owing to the constitutional factors concerned If the causal factors—dietetic drug contact emotional—can be altered or removed there is a reasonable prospect of success in cases where this is impossible for reasons of age environment or disposition the outlook is proportionately bad

Diagnosis —*On the scalp* the diagnosis is made from ringworm in children by examination for broken hairs microscopy and Wood's light examination Psoriasis of the scalp causes palpable discoid lesions with heavy scaling whereas in seborrhoeic dermatitis the lesions are impalpable except when impetiginised On the trunk the diagnosis is from pityriasis versicolor pityriasis rosea ringworm psoriasis and para psoriasis (*q v*)

Treatment —The general treatment consists of dietetic adjustment the withdrawal of any harmful contact or drug irritants and emotional adjustments where necessary or possible

The diet should be low in carbohydrates and fats and sufficient in protein and vitamin content The urine should be tested for albumin and sugar Alcohol chocolate, fried and spiced foods should be taken in strict moderation Vitamin B

complex and crude liver injections may help in cases with a history of dietetic im balance or with evidence of hepatotoxic effects from a drug or other cause

Local treatment for the scalp—a shampoo of 1 per cent cetrimide is most useful and this substance may be used for cleansing other affected areas of the skin

For pityriasis simplex a lotion such as that of salicylic acid and perchloride of mercury (N F) is useful rubbed in daily and gently with the finger tips

For pityriasis steatoides of the scalp the ointment of salicylic acid and sulphur (N F) is most useful but the strength should be reduced to 1 per cent when using it on children s scalps

For impetiginised lesions it is advisable to have a culture made and to use the best antibiotic according to the findings Until this result is to hand the use of 1 per cent cetrimide followed by zinc and copper lotion (D alibour water) as a local application should help

For infective dermatitis on the *trunk* the emulgent base in salicylic acid and sulphur ointment is likely to aggravate and recourse should be had to 1 per cent of sulphur or ichthammol or to 0 1 per cent of pyrogallol in calamine liniment or if there is more obvious infection Vioform cream (3 per cent) (Ciba) is often helpful

For *intertriginous dermatitis* antibiotics are best held in reserve until the cultural findings are known and recourse should be had to fungistatics such as magenta paint or to brilliant green 1 per cent in zinc paste or to Vioform cream When the moist phase has passed the patient should apply a bland dusting powder for example boric talc powder or salicylic acid dusting powders and keep the opposing skin surfaces apart with uplift breast supports and suitable clothing or gauze dressings

OTHER FORMS OF ECZEMATOUS DERMATITIS

The term eczema implies a boiling over of the skin and should be confined to spontaneous eruptions characterised clinically by papulo vesiculation and microscopically by spongiosis This definition excludes all primarily frictional dermatoses such as lichen simplex (neurodermatitis circumscripta) and disseminated neuroderma titis (atopic dermatitis)

A condition of uncertain status is exudative neurodermatitis in which extensive areas of exudation and crusting are present chiefly on the more distal parts of the limbs It is found in persons with hysterical traits and appears to be an exudative response to emotional stimuli particularly self pity

NUMMULAR ECZEMA

Nummular (discoid) eczema (infectious eczematoid dermatitis) is an outbreak of papulo vesicles often confined to the more hairy surfaces of the limbs particularly the forearms and legs but sometimes becoming more generalised Sometimes dis crete shotty vesicles appear as well A chemical contactant cannot be incriminated and the malady is probably related more to sensitivity to skin resident organisms particularly *Staphylococcus saprophyticus* and monilia

Infectious eczematoid dermatitis is a disorder closely related to nummular eczema in which the discharge from an area of infective dermatitis produces a mixed eczema tous and infectious (impetiginous) reaction wherever it touches

Treatment —Nummular eczema responds best to nonsensitising bacteriostatic and fungistatic remedies such as chlortetracycline ointment chloramphenicol cream Vioform cream magenta paint or brilliant green in zinc paste Symptomatic treat ment should also be given to relieve depression if present by dextroamphetamine 5 mg in the morning and insomnia from itching by barbiturates or promethazine

hydrochloride in the evening In resistant forms a course of intravenous T A B 25 million, 50 million and 100 *million organisms at 5 to 7 days' intervals may bring* about a remission X irradiation in fractional doses is often effective

POMPHOLYX (DYSIDROSIS)

This is a vesicular eruption of the palms and of the palmar and lateral aspects of the digits and of the under surfaces of the feet It is often recurrent.

Ætiology and Pathology—This is a skin reaction which may be secondary to fungous infection of the feet (mycide) it may be a manifestation of eczematous dermatitis exogenous or endogenous, or it may be of psychogenic origin an hysterical phenomenon serving the purpose of preventing the sufferer from performing some task which is distasteful

Histologically there is spongiosis as in eczematous dermatitis elsewhere The vesicles remain intact owing to the thick horny layer above them There is no evidence of obstruction of the sweat ducts, except secondarily through pressure from the *adjacent vesicles but clinical* experience of the seasonal incidence and of aggravation by heat, exertion or anxiety suggests that some abnormality of the sweat apparatus (so far unexplained) plays a part in the pathogenesis

Clinical Picture—There are vesicles of uniform size, resembling frog spawn in the skin of the palms and fingers and on their lateral aspects The backs of the hands may be quite normal The feet may show a similar condition in a comparable distribution The affected areas do not sweat There is considerable itching until the fluid is either reabsorbed or discharged by rupture of the vesicles Coarse peeling follows and resolution may occur or the whole process may be repeated

Course and Prognosis—This depends on the cause whether it be fungous infection eczematous hypersensitivity or an hysterical personality The form due *to fungous infection does well when the infection is controlled* The other two forms tend to recur unless a sensitising substance can be found and subsequently avoided, or unless the patient can be brought into better adjustment with life situations

Diagnosis is from pustular psoriasis, erythema multiforme and tinea pedis The *former presents with golden yellow pustules from the beginning*, whereas in pompholyx the vesicles are skin coloured at first

In erythema multiforme there may be large bullæ and there is also erythema, which is absent in pompholyx

Tinea pedis presents with large bullæ in the roofs of which mycelial threads *may* be found on microscopy but the same foot may also have on it many *small vesicles* of pompholyx type (mycide) in which fungus cannot be found Tinea pedis is *often* asymmetrical its mycide symmetrical idiopathic eczematous and psychogenic pompholyx are symmetrical but contact eczematous dermatitis is often asymmetrical

Treatment is bland and supportive by Lassar's paste hydrous ointment or calamine lotion while the fungous infection is being controlled while irritants and sensitisers are being avoided or while the patient is receiving psychotherapy If infection becomes superimposed—and this often occurs with purulent blebs lymphangitis and lymphadenitis—the part should be elevated and kept at rest Soaks *for* 10 minutes in a 1 in 6000 solution of potassium permanganate are useful and sulphonamides or penicillin may have to be used systemically

In many patients it is necessary to give sedatives for example phenobarbitone in a dose sufficient to control itching and to provide sleep

AUTOLYTIC ECZEMA (ECZEMATIDE)

This is a widespread papulo vesicular eruption arising from absorption of products from an area of erosion or of ulceration The absorbed products may originate from

organisms on the skin or they may result from the breakdown of body cells The process is more likely to occur with the use of certain substances on the skin particularly sulphonamides flavine paraphenylenediamine benzocaine mercurials etc but it may even develop from the occlusion of a moist area by soft paraffin which suggests that the substances applied are not primarily responsible but that they hasten cellular disintegration or encourage infection Autolytic eczema typically arises from faulty treatment of ulcers or eczema (eczematide) on the legs but it also arises from over treatment of extensive abrasions second degree burns herpes simplex eczematous or infective dermatoses

Prevention and Treatment—This condition is preventable by avoidance of the use of powerful sensitising agents on the surface such as sulphonamides flavine picric acid mercurials and benzocaine also by not using occlusive soft paraffin dressings over moist areas

It is best treated by application of oily calamine the use of sedatives and intramuscular crude liver extract injections

ENDOGENOUS ECZEMA

A widespread papulo vesicular eruption for which no immediate contact cause can be found Sometimes the epidermal sensitisation has arisen from the administration of a drug (for example sulphonamide) previously used topically but often the most careful history fails to elicit any cause in the form of a focus of infection drug food or metabolic disorder Such patients are often tense over active obsessional personalities and this make up seems to be of ætiological significance

Treatment—Bed rest is advisable in the more severe forms Suspected foci of infection are treated and the patient is given a diet of high protein and vitamin content which is not water retaining The intake of fats and carbohydrates alcohol coffee and condiments is reduced Sedatives are given by mouth and bland local applications are used T A B injections are sometimes useful If the condition is believed to be an exudative neurodermatitis the patient should be encouraged to lead an active life and to discard feelings of self pity if as often happens these are present Dextro amphetamine 5 mg after breakfast is a useful remedy for this type of patient

INFANTILE ECZEMA

The term covers infective eczema of infants and the earliest papulo squamous stages of the condition called Besnier s prurigo later in life Both forms may coexist

In the infective variety there is greasy scaling of the scalp and sometimes of the face chest and flexures The child is usually overweight

In the pruriginous form there is a widespread erythemato papulo squamous rash with exudation and crusting affecting particularly the face and parts of the limbs and body most accessible to the infant s efforts at scratching and rubbing that is the shoulders elbows wrists and hands knees legs and feet The trunk is only slightly affected with a blotchy erythemato papular eruption

Ætiology—Infantile eczema is in part due to inherited abnormalities in part to an unfavourable emotional environment and in part to faulty feeding practices It is seldom due to allergy to foodstuffs

In the infective form an excess of fat or carbohydrate in the diet is often an important factor This may occur because the child is weaned at an early age on to a full cream milk because of failure of lactation It may also occur at or about 6 months because the child is given excess of cereal foods The skin as a result becomes

susceptible to infection by organisms resident on the skin (*monilia* and *Staphylococcus saprophyticus*)

In the rare allergic form milk (lactalbumin) or cereal products are usually responsible

The more common pruriginous form (atopic eczema) is in part due to an inherited predisposition and in part due to an unsatisfactory mother child relationship in which an emotionally labile mother who is unable to give the child the steady and unselfish affection it needs clashes with a child of higher than average intelligence and peculiarly prone to itching and frenzied rubbing and scratching whenever deprived of pleasurable activities or of affection Pruriginous eczema sometimes complicates xeroderma

Course and Prognosis—The infective type tends to clear up with suitable dietetic adjustments and local treatments, but it may relapse

The allergic form responds to the withdrawal of the proven allergen provided this is the only cause

The pruriginous form tends to get better at 1½ to 3 years when the child can do more for itself in exploration of its environment There is however, often a recrudescence at or about puberty this time with a preponderance of facial and flexural involvement (Besnier's prurigo)

Diagnosis—The affixment of the label 'eczema' offers no difficulty the problem is to apportion blame to inheritance environment diet and infection and this depends on a careful review of the history and signs

Treatment—In the infective form the protein vitamin and mineral content of the diet should be rendered adequate but fats and carbohydrates should be reduced Thus egg yolk bone broth, sheep's brains, tripe and pounded fish may be recommended with spinach puree and other sieved vegetables, cereals full cream milks or addition of sugar are best avoided half cream milk being offered instead

Local treatment depends on the degree of infection If this is severe the most suitable antibiotic should be applied If milder, the skin may be cleaned with a 1 per cent solution of cetrimide, and 1 per cent of salicylic acid and of sulphur in an emulgent base applied Later, oily calamine lotion can be substituted

The child should be cleaned as a routine with olive oil, and a superfatted soap used when necessary

The diagnosis of allergic eczema is made by elimination diets Cow's milk is first omitted If there is improvement lactalbumin of milk is suspected as the cause If there is no improvement cow's milk is given alone for 24 hours and then one item is added each day until any aggravating factor or factors are found Those are then omitted from the diet If cow's milk is the cause goat's milk can be substituted or a lactalbumin free product (for example Allergilac)

Pruriginous eczema depends for its control on adjustments in the mother child relationship as well as on all the physician can do by bland local applications restraining appliances and sedatives The mother and all around the child should be encouraged to generate a calm and unselfishly affectionate atmosphere The child should be kept fully occupied with suitable toys on which he can relieve his aggressive urges but in infancy it may be necessary to tie the limbs with broad crepe bandages to the sides and foot of the bed providing adequate protection to the skin where they are applied so that damage cannot occur It is only in this way, and with sedation pushed to the limit that the child can be kept from rubbing and scratching its face and limbs until they are raw Eczematous children tolerate sedatives such as phenobarbitone in higher doses than the more normal child, and a dose of gr ¼, three or four times a day for a child 12 months old is nothing unusual In milder cases the elixir of Benadryl or of promethazine hydrochloride or a chloral and potassium bromide mixture may be sufficient

Local applications should be bland and free from sensitising properties The

watery or the oily calamine lotion zinc cream zinc paste or hydrous ointment are all useful at times Hydrocortisone ointment 1 to 2 5 per cent has been reported to be effective

Where treatment is not proving successful at home a period in hospital is sometimes of great value but this has to be balanced against the risk of these children getting widespread pyogenic or virus skin infections to which they may succumb

ERYTHEMA INFANTUM (NAPKIN ERUPTION)

Erythema of the napkin area may be due to infection or to chemical irritation The *infective form* involves the depths of the folds of skin It may be a part of pemphigus neonatorum The chemical irritative form affects the summits of the folds of skin buttocks thighs etc Sometimes the cause is urea splitting organisms in the infant s fæces The resultant ammoniacal urine causes a contact dermatitis (Jacquet s erythema) In other cases excesses of fat or sugar in the infant s diet may result in stools that irritate the skin Occasionally insufficient rinsing of the napkins after they have been washed is responsible for an alkaline or detergent dermatitis

Treatment —*In the infective form cleansing with 1 per cent cetrimide and the* application of an inert dusting powder is often sufficient or the appropriate antibiotic can be applied after cultural examination

In the chemical irritant form treatment depends on the cause but further aggravation must be prevented by the application of zinc and castor oil cream to the infant s buttocks

Dietetic adjustments may be necessary or greater care in rinsing the napkins In Jacquet s erythema soaking the napkins in a quaternary ammonium compound or in saturated boric acid solution before use is effective The napkins should be rinsed thoroughly after these procedures before use

HYPOSTATIC ECZEMA AND ULCERS ON THE LEGS

Defective venous return of blood from the legs leads to a gradual deterioration of the vitality of the skin of the lower parts of the calves and ankles resulting in the various clinical conditions known as hypostatic eczema Minor wounds of the legs are always apt to take longer to heal than similar wounds on the upper limbs even in healthy youths This tendency to poor healing is accentuated if there is any deficiency of the veins either through incompetent valves or deep thrombosis each of which may be responsible for the development of varicosities but varicosities in themselves are not the cause of eczematous and ulcerative changes eczematous changes are due in the first place to chronic congestion and anoxæmia while ulceration is due to superficial venous thrombosis causing a focal necrosis in the dermis

The congested anoxic legs tend to itch scratches or other minor injuries do not heal but tend to exude Mild secondary infection causes an aggravation of the condition and many patients treat themselves not by rest with elevation of the limbs or by suitable supports to the legs but by local applications one or other of which in time sets off a contact eczematous reaction Further misguided treatment with antiseptics and other potential sensitisers results in the picture of chronic exuding eczema of the legs

With appropriate treatment the exudation stops and is replaced by coarse peeling from the swollen reddened skin Gradually the peeling becomes less conspicuous and provided lichenification does not develop ultimately it stops the leg being left pigmented and possibly somewhat indurated but dry

Ulcers may develop from abrasions scratch marks cuts or bruises on the leg

The skin below and behind the medial malleolus is a specially vulnerable area no doubt in part because there may be a downward back pressure from the pumping action of the calf muscles and in part from the poor support and lack of rest supplied by the underlying tendons Stasis and local œdema are the most important factors in the non healing of ulcers of the leg and secondary infection is usually a minor feature, but sometimes healing is prevented by a heavy mixed infection of cocci *Ps pyocyanea* and *Proteus*, or streptococci may gain entry and cause cellulitis followed by chronic solid œdema of the part (*elephantiasis nostras*)

Diagnosis —Most ulcers on the legs are hypostatic and related to thromboses varicosities and chilblains but some are arteriosclerotic as shown by absence of pulsation in the dorsalis pedis artery and radiographic evidence of calcification This may occur with or without diabetes

Gummatous ulcers are often higher up the calf serpiginous in outline, ham coloured and appear as if punched out Lupus vulgaris, sporotrichosis and halogen granulomata can all cause leg ulcers

Rodent ulcers occasionally form on the legs and nodes of Hodgkin's disease or some other reticulosis may break down in that situation

Pseudoepitheliomatous hyperplasia is a warty condition clinically and histologically resembling carcinoma but due to over treatment of an ulcer with sensitising local applications It clears up when the irritant is withdrawn

Ecthymatous ulcers are moist, with dirty sloughs and no signs of granulations

Treatment *of hypostatic eczema* is supportive by suitable elastic hose or bandages with bland non absorbable local applications, for example calamine liniment

If the exudation persists in spite of this an ointment of 12½ per cent of solution of aluminium acetate with 37½ per cent of zinc paste and 50 per cent of lanolin may prove effective In the scaling, lichenified stage X irradiation in fractional exposures may help Unna s gelatin paste or zinc paste bandages are u eful in the subacute or chronic stages but adhesive bandages should not be used The patient needs to wear a support to the leg indefinitely or in suitable cases provided the deep veins are patent the varicose veins may be given surgical attention by injections and ligations

Treatment of hypostatic ulcers aims at reducing local œdema Tulle-gras is applied to the ulcerated area with an overlying gauze orthopædic felt or sponge rubber pad covering the ulcer and the skin around the whole leg being firmly bound with an elastic bandage The patient is encouraged to take exercise and is warned about the bad effects of prolonged standing Massage to the surrounds of the ulcer and to the limb as a whole is helpful Any infective element is controlled by the appropriate antibiotic Any excessive granulations are reduced by a silver nitrate pencil

Surgical treatment of any varicose veins is carried out in selected cases

COCCAL INFECTIONS

In health the intact skin is able to resist invasion by organisms falling upon its surface Infections result either from breaks in the surface of the skin or from some abnormality of its acid mantle This mantle is formed by the continuous slow extrusion of sebum from the sebaceous glands through the pilo sebaceous orifices and the emulsification and spread of the sebum over the surface by means of the sweat

Dehydration of the surface is another important factor in the prevention of infections *Sweat retained on the surface* particularly in body folds provides ideally moist warm conditions for bacterial growth, and sweat when decomposing by bacterial growth becomes alkaline, which further encourages the bacteria

Coccal infections of the skin are encouraged by anything that causes breaks in the surface such as clumsy hair cutting or shaving rough clothing scratching or

dermatitis leading to fissuring also of importance are the qualitative and quantitative abnormalities of the sebum which occur in seborrhœic dermatitis and xeroderma and excessive sweating particularly in obesity when skin surfaces chafe and rub off the superficial epidermal cells

Skin infections are more common with diabetes mellitus in toxic states such as uræmia in states of nutritional deficiency and in blood diseases for example leukæmia

Before considering infections at various anatomical situations in the skin it is well to remember that in all cases of severe or widespread coccal infection a cause must be looked for locally (infestations, itchy dermatoses) and generally (diabetes uræmia leukæmia anxiety neurosis etc) Attention must also be paid to potential carrier sites of staphylococcal infection especially the hairy vestibule of the nose

IMPETIGO VULGARIS (IMPETIGO CONTAGIOSA)

Impetigo is a coccal infection of the epidermis sometimes involving the ostia of the pilosebaceous follicles (follicular impetigo) or of the sweat ducts (infected miliaria rubra Bockhart s impetigo)

Ætiology and Pathology—Impetigo vulgaris is usually a disease of children but may occur in adults with the seborrhœic diathesis (seborrhœic impetigo) It usually follows some break in the skin s surface caused by insect bites scratching or the rupturing of herpetic bullæ Purulent discharges from the nose ears or eyes are often responsible or the infection may be transferred to the face and other exposed parts from a paronychial whitlow Nasal diphtheria may be complicated by impetigo

Clinical Picture—The lesions of impetigo consist of golden or dirty greenish grey stuck on crusts discoid polycyclic or annular scattered over the face scalp or limbs amongst areas of normal skin Occasionally there are intact bullæ containing thin pus Similar lesions may be present in the nostrils It is not possible on clinical grounds alone firmly to differentiate between staphylococcal and streptococcal impetigo Although streptococci may be present in the early stages *Staphylococcus pyogenes* usually predominates in any culture that is made and is often grown in pure culture

At the angles of the nose or mouth and behind the ears fissures may form with exuding red sodden or crusted skin nearby

Course and Prognosis—Without treatment impetigo may continue for several weeks In every case the precipitating cause must be dealt with for example pediculosis otorrhœa rhinorrhœa or scabies because once this is under control the elimination of the coccal infection is a simpler matter Use of the appropriate antibiotic then leads to clearance in 3 to 7 days Occasionally impetigo is complicated by nephritis Impetigo should be investigated epidemiologically in order to control the outbreak in a family or school Contacts should be examined for banal lesions septic fissures running noses etc

Diagnosis—It is important to differentiate impetigo from herpes simplex and from eczematous dermatitis on the face whether infected or not

In herpes simplex the vesicles often remain intact for a while they are grouped and contain clear fluid Impetigo may originate from infection of ruptured herpes vesicles but eczematous dermatitis may also begin from the faulty treatment of herpes simplex with antiseptics or antibiotics

In eczematous dermatitis the lesions at first spread in continuity from the site of application of the irritant but later they may erupt symmetrically in explosive fashion In impetigo the spread is more irregular and impetuous skipping areas of normal skin with the effect that individual lesions develop rapidly by peripheral spread at several sites of skin inoculation

Treatment—If pediculosis or scabies is present it should be dealt with first Any residual infection that persists may then receive attention

If an intensely itchy skin disease such as prurigo coexists, it should be controlled by suitable sedatives by mouth and the superimposed impetigo only treated for as long as is necessary before proceeding to suitable treatment of the underlying dermatosis

Ideally a culture should be made and the organisms tested for their susceptibility or resistance to various antibiotics, but with a short term disease such as impetigo the usual practice is to apply the antibiotic believed by the prescriber to be most effective Chloramphenicol, chlortetracycline (Aureomycin) and oxytetracycline (Terramycin) are all effective in many cases but, in common with penicillin they are unsuccessful in those infections due to resistant strains which are becoming more common

Antibiotics are far from being the *sine qua non* in the treatment of impetigo Simple desiccation may be quite effective, and for this purpose calamine lotion is effective with the addition of 0 1 per cent of mercuric chloride if desired Calamine liniment may also be used, or zinc paste with 2 per cent of salicylic acid (Lassar s paste) To the last named may be added 1 per cent of ammoniated mercury or of brilliant green

Loose crusts and intact bullæ should be removed before any remedies are applied For this purpose normal or slightly hypertonic saline may be used or a 1 per cent. solution of cetrimide which has the added advantage of its antiseptic properties

No antibiotic should be persisted with for more than 3 days if it is not giving satisfactory results Failure to respond implies resistant organisms and continuing the use of the antibiotic may lead either to a spread of infection or to the development of eczematous hypersensitivity Two per cent of silver nitrate in spirits of nitrous ether is useful as a paint for application to fissures

PEMPHIGUS NEONATORUM (IMPETIGO NEONATORUM)

This is a form of staphylococcal impetigo affecting newborn infants highly infectious and having a considerable mortality rate

Ætiology—The infection begins from an extraneous source for example a cutaneous or nasal infection or carrier state in a medical or nursing member of a maternity unit a visitor, a lay worker or one of the patients One attendant may infect several infants

Clinical Picture—Large bullæ containing thin pus cover the body surface and pink, shiny moist areas indicate where bullæ have ruptured The widespread severe and often fatal form of the condition resembles exfoliative dermatitis (dermatitis exfoliativa neonatorum of Ritter) It has recently been suggested, however that Ritter s disease is caused by the application of napkins which have previously been soaked in boric acid

Course and Prognosis—Premature and inadequately treated infants may succumb to the infection but as a rule patients respond to antibiotic therapy A careful search must be made for the primary source for carriers and possible conveyance by fomites As a precaution, all in attendance on newborn infants should wear efficient surgical masks

Diagnosis is from congenital syphilis in which the pemphigoid lesions occur on the palms and soles as well as elsewhere Other signs of congenital syphilis may be present including rhagades snuffling etc

Treatment is by the appropriate antibiotic locally also systemically if this seems advisable Good nursing is essential and protection of the child from chilling when dressings are being done

IMPETIGO PITYROIDES (PITYRIASIS ALBA)

This consists of scaly depigmented discs which occur on the faces of children The lesions are believed to be streptococcal and mildly infective, but drying winds

and the excessive use of soap seem to play an equally important part in their production

Treatment—The lesions usually respond to the application of weak ammoniated mercury ointment or to 2 per cent of solution of coal tar in Lassar's paste

PYOGENIC PARONYCHIA (see Diseases of the Nails)

ECTHYMA

This is a coccal infection originating from the surface and affecting the dermis leading to necrosis ulceration and scarring Trauma is an important predisposing factor

Clinical Picture—This malady is more common amongst under nourished ill-cared for children and amongst individuals of low intelligence than among clean and normally intelligent persons It usually affects the legs where one or several areas of dirty grey crusting may be seen with a purulent discharge and red surrounds Later the crusts become detached leaving shelving ulcers with an inflammatory rim and a sero purulent base There may be regional lymphadenopathy Ecthyma may also occur in adults suffering from pediculosis or from infection of traumatised legs (for example desert sores)

Course and Prognosis—If untreated the condition may persist indefinitely and it may spread as impetigo or furunculosis on other parts of the body

Diagnosis—An ecthymatous syphilide must be excluded

Treatment—Having excluded any parasitic infestation attention is directed to any malnutrition and uncleanliness that may exist

For local treatment cleansing with 1 per cent cetrimide is indicated followed by application of the antibiotic most suitable according to the cultural findings This is likely to prove effective more rapidly than nonspecific remedies such as eusol compresses or a lotion of sodium hypochlorite Desiccating measures may also be employed The nails should be kept closely trimmed and attention paid to any infective foci in the nostrils or paronychial folds

FOLLICULITIS

Coccogenic folliculitis is one form of sycosis barbæ (folliculitis profunda) the other being mycotic folliculitis Folliculitis may also be superficial (ostio folliculitis Bockhart's impetigo)

FOLLICULITIS BARBÆ

Clinical Picture—Folliculitis barbæ is a chronic staphylococcal inflammation of the depths of the hair follicles in the beard region Folliculitis profunda may also occur at other sites for example the nucha and the pubis

Discrete follicular papules and pustules are present and from them hairs protrude The lesions may be grouped or diffusely confluent all over the beard area Tender nodules may form In long standing cases due to antibiotic resistant strains the efforts at cure with sundry medicaments may end in a mixed condition of folliculitis and dermatitis presenting as diffuse redness and exudation or scaling interspersed with follicular pustules

Ætiology and Pathology—Shaving trauma and staphylococcal infection

Course and Prognosis—The progress of folliculitis depends on the susceptibility or resistance of the causal organisms to antibiotics In the majority relief can be obtained with one antibiotic or another but it is always wise to have a culture made and the antibiotic sensitivity of the organisms investigated before starting treatment especially as antibiotic resistant strains of staphylococci are becoming more

common Furthermore, many individuals with folliculitis show other signs of the "seborrhœic" diathesis which indicates that they are susceptible to infection of the skin Sycosis in them may present with less frankly purulent lesions the organisms responsible being less potent strains of *Staphylococcus aureus* or even *Staphylococcus albus* and not the coagulase positive *Staphylococcus aureus* usually met in folliculitis

If folliculitis relapses in seborrhœic individuals it may be because of invasion by a different strain of organisms with different antibiotic sensitivities For this reason, it is advisable to repeat the culture and antibiotic sensitivity tests in any relapse

In every case of staphylococcal folliculitis it is essential also to take a swab and to culture the organisms from the nasal vestibule and to treat this carrier site of staphylococci with the appropriate antibiotic It is not necessarily true that the organisms cultured from lesions on the skin are alone responsible for the development of that lesion A coccal infection may be superimposed on a syphilide, and organisms such as *Staphylococcus saprophyticus* and Gram negative organisms of the coli group *Ps pyocyanea* or *Proteus* may be secondary invaders of devitalised tissue Fæcal *contaminants do, however, seem to play a significant role in some cases*

Diagnosis has to be made from impetigo mycotic folliculitis chemical folliculitis foreign body reactions due to ingrowing hairs infected acne and syphilis In impetigo the lesions are superficial and not necessarily follicular In mycotic sycosis the patient gives a history of contact with cattle the lesions are much more acute and œdematous and hairs can easily be pulled out from the follicles fungus spores may be found (often with some difficulty) on removing infected hairs

Chemical folliculitis is usually due to over treatment or to faulty treatment of a non infective dermatosis of the beard area with antibiotics or antiseptics It is recognised by the presence of diffuse dermatitis and much serous exudate as well as folliculitis

Foreign body reactions due to ingrowing hairs are most common in coloured men with curly hair running in every direction which, on shaving tends to become embedded in the skin This especially occurs on the sides of the neck under the chin line but may also occur on the face It occasionally occurs in white men particularly those who shave very closely against the grain Embedded hairs are visible on inspection with a hand lens and their free ends can be extracted with a needle Culture in such a case usually grows saprophytic organisms or coliforms

Infected acne occurs in the skin immediately adjoining the beard area but may coexist with folliculitis barbæ The presence of comedones is an essential feature in the diagnosis of acne

Syphilis may in the secondary stage present with pustulation and frambœsiform crusts at the cleft of the chin Its presence should be suspected from any atypicality of the lesions and any signs of syphilis elsewhere Lupoid sycosis is differentiated from lupus vulgaris by the presence of atrophic scarring with occasional pustules and by the absence of apple jelly nodules

Treatment consists of the application of the appropriate antibiotic to the lesions and if necessary to the nostrils three or four times a day This treatment should be persevered with for a fortnight after apparent clinical cure even after that interval, *relapses are common in seborrhœic* individuals With penicillin a lotion is often more effective than a cream and less likely to sensitise the skin but it may prove too drying With chloramphenicol chlortetracycline and oxytetracycline ointments *or creams are usually effective* and they are pleasant to use

Other applications which may prove relatively effective include quinolor ointment Vioform cream and ammoniated mercury but they all have in varying degrees *a tendency to sensitise the skin* Zinc and copper lotion (D alibour water) is useful as an after shave lotion In very severe or resistant forms of folliculitis barbæ it may be advisable for the patient to use an electric razor Growing a beard is a satis

factory alternative The use of X rays in folliculitis barbæ is contraindicated both in fractional and epilatory doses

OSTIO FOLLICULITIS (BOCKHART S IMPETIGO)

Ostio folliculitis is a staphylococcal infection of the orifices of the follicles

Ætiology —Ostio folliculitis is caused by stimulation of the epidermis by oil adhesive plasters or other surface irritants It is often a complicating feature of prickly heat (*miliaria rubra*)

Clinical Picture —Discrete superficial pustules are present at the orifices of hair follicles Hairs penetrate the pustules On rupture superficial erosions are left The lesions are often grouped but sometimes extensive There is often an associated keratosis follicularis or acne because the irritants causing the folliculitis also stimulate epithelial proliferation at the ostia The sites usually affected are the forearms and thighs

Course and Prognosis —This depends on the future avoidance as far as possible of contact with irritants such as oil adhesive plaster powerful degreasers and de hydrators The worker should be given facilities to wash parts exposed to oil im mediately after work is finished he should be discouraged from postponing washing until he gets home perhaps after a considerable journey The condition is then likely to clear

Treatment —Parasitic infestation must be excluded A culture should be made and the appropriate antibiotic used Vioform cream is sometimes effective and D alibour water is useful followed by lead and calamine lotion

PILI INCARNATI (see Folliculitis Barbæ)

Treatment —The only treatment of value for this relatively mild but annoying condition is the avoidance of close shaving particularly with the skin under tension The shaver should aim at the sort of result obtained by one shave with the grain Electric razors are not necessarily an advantage

BOILS AND CARBUNCLES

A boil (furuncle) is a staphylococcal infection of a sebaceous gland proceeding to a perifollicular abscess sloughing of the hair papilla and of the pilosebaceous follicle and its replacement by scar tissue

Furunculosis is a condition of multiple localised or widespread boils A carbuncle is a localised group of boils which by their mutual pressure cause sloughing of exten sive areas of skin and subcutaneous tissue with much constitutional disturbance

Ætiology and Pathology —Boils are usually due to some local breakdown in the skin s protective mechanism Carbuncles are usually due to some general lower ing of resistance Thus boils may be secondary to scratch damage in an itchy skin condition whether it be parasitic infestation dermatitis or prurigo or they may result from local damage arising from shaving or haircutting rough clothing oil or dirt A carrier site of staphylococci in the nose is often the source from which the skin is inoculated and furunculosis may set a problem in domestic epidemiology in which the sharing of face flannels towels etc may prove to be responsible for the spread of infection within the family In every case of furunculosis and more espec ially with carbuncles attention should be directed to the possible presence of diabetes renal disease leukæmia or nutritional deficiency either of insufficiency or of imbalance

Clinical Picture —A boil begins as a painful red nodule which enlarges and becomes hard and tender At its centre a small papule or papulo pustule is visible penetrated by a hair Induration and pain cause difficulty in moving the affected

part After 36 to 48 hours the centre softens, a small scab or slough detaches and a purulent discharge begins In another 36 to 48 hours the 'core' or pilosebaceous slough is extruded the purulent discharge and induration lessens and the boil heals with a varying amount of scar formation

A carbuncle begins with greater constitutional disturbance Instead of a nodule there is a brawny plateau in which several follicular pustules can be seen The mass enlarges and a shelving induration with œdema extends for some way around Softening and liquefaction of the mass may (in patients treated by local application only) take days or even a week or two, but sooner or later a large slough forms and is gradually detached or many points of suppuration develop, with subsequent extensive scarring Smaller boils and follicular pustules around the main lesion often form as a result of auto inoculation

Course and Prognosis —These depend on the cause and the ease or difficulty of its removal With itching due to infestations, it is easy with itching due to emotional conflict it may be extremely difficult A carbuncle in a debilitated patient is a serious and sometimes fatal condition

Diagnosis —A boil or carbuncle has to be diagnosed from a malignant pustule (anthrax) In the latter, the onset is more rapid and the constitutional symptoms are more marked while the history of exposure to wool or hides makes the diagnosis likely Culture or even a direct smear will usually reveal the bacilli but treatment should be started on clinical grounds alone, without awaiting cultural confirmation

The primary tuberculous complex resembles an indolent boil but the youth of the sufferer, a history of contact, the lymphadenopathy draining the site of inoculation and the resistance to antistaphylococcal measures should arouse suspicion

Treatment —In every case the cause should be looked for and treated if possible Glycosuria or albuminuria malnutrition or leukæmia should all be excluded If itching preceded the boils this should be investigated Occupational hazards unsuitable clothing and faulty hygiene practices should receive attention

Severe boils and carbuncles are best dealt with by systemic penicillin or some other suitable antibiotic depending on organismal sensitivity tests Smaller lesions are better treated by local remedies Penicillin injections are a passive treatment having no value for stimulating the reactivity of the host in fact the converse sometimes applies penicillin injections being followed on cessation by a crop of further boils of even greater severity For this reason it is a mistake to give penicillin at once without first investigating the cause of the infection and the susceptibility of the organisms to antibiotics Vaccines staphylococcal toxoid manganese injections and tin by mouth have a reputation for relieving furunculosis but their effects are most uncertain

Local treatment should aim at resolution of the lesions with minimal discomfort and with the avoidance of further contamination of the skin by the pus coming from the boils Softening or maceration of the skin must be avoided and boracic fomentations kaolin poultices and glycerin and magnesium sulphate dressings often do more harm than good Dry heat may be applied with precautions to prevent burning or hot bathing may be used In the intervals between such procedures the following paint may be applied to and around the boil to control the local infection and to keep the surface of the skin dry and hard

Mercuric chloride	0 1 per cent
Brilliant green	1 0 per cent
75 per cent industrial spirit to	100 0 per cent

Once the boil is discharging dry dressings frequently changed are used and chlortetracycline cream 1 per cent or the above mentioned paint, applied to the skin around

Surgery in particular crucial incisions is contraindicated and the only justifiable

manipulative procedure is the encouragement of separation of the slough as soon as possible

Boils on the nose and upper lip need especial care because of the risk of infection spreading by communicating veins to the interior of the skull with fatal results On no account should they be subjected to pressure The patient should be rested and systemic antibiotic treatment started at once Locally the gentle application of warmth is justifiable

HYDRADENITIS SUPPURATIVA

This is an infection of apocrine glands in the axillæ or perineum often giving rise to deep abscesses which tend to track beneath the skin

Ætiology—The condition is more common in women than in men The apocrine glands are susceptible to psychosexual and endocrine stimuli Infection is unlikely to arise without some other factor being present such as chemical irritation from depilatories deodorants or the rubber of dress protectors

Clinical Picture—In one or both axillæ or at the perineum is an irregularly nodular surface with tenderness and areas of induration and of fluctuation Pus may be discharged from sinuses and there is a marked tendency to tracking irregular scarring chronicity and recurrence

Treatment—Any chemical irritation of the region should be avoided Culture and use of the appropriate antibiotic in a cream is usually effective or 0 1 per cent. mercuric chloride and 1 per cent brilliant green in 75 per cent industrial spirit may be applied In resistant cases X rays 100 r up to four times at weekly intervals may help In the most chronic forms success has followed excision of the affected tissue with plastic repair

DERMATITIS VEGETANS

This is a condition of irregular epidermal hyperplasia overlying an area of infected dermatitis where the tissue reactions are vitiated by senility or local disease in particular lymph stasis

Clinical Picture—Over an extensive area of skin there is redness with a pustular exudate and an irregular warty or even pseudo epitheliomatous hyperplasia of the epidermis Culture may reveal a mixed infection in which Gram negative organisms such as *Ps pyocyanea* and *Proteus* are prominent

The condition may develop as a complication of pre existing skin conditions for example pemphigus vulgaris

Treatment is that of the underlying condition and elimination of the causal organisms In the form secondary to lymphatic blockage in the leg the best that can be expected is an elephantiatic leg and sometimes amputation may have to be considered as likely to give the best results whereas retaining the limb may bring with it much toxicity and secondary anæmia

PYODERMA GANGRENOSUM

This is a rare condition of burrowing colliquative necrosis and ulceration of the skin either due to symbiosis between anaerobic streptococci and hæmolytic streptococci (Meleney s ulcers) or due to the loss of fluid and electrolytes that occurs in acute exacerbations of ulcerative colitis or dysentery or when massive intestinal hæmorrhages occur in the former disease A similar condition has rarely been reported in extensive cachectic states with varicella There is leucopenia due to marrow depression

Treatment is of the primary condition Replacement of fluid and electrolytes blood transfusions and antibiotics are necessary With control of the loss of fluid and electrolytes healing usually begins spontaneously

part After 36 to 48 hours the centre softens, a small scab or slough detaches and a purulent discharge begins In another 36 to 48 hours the ' core ' or pilosebaceous slough is extruded, the purulent discharge and induration lessens and the boil heals with a varying amount of scar formation

A carbuncle begins with greater constitutional disturbance Instead of a nodule there is a brawny plateau in which several follicular pustules can be seen The mass enlarges and a shelving induration with œdema extends for some way around Softening and liquefaction of the mass may (in patients treated by local application only) take days or even a week or two but sooner or later a large slough forms and is gradually detached or many points of suppuration develop with subsequent extensive scarring Smaller boils and follicular pustules around the main lesion often form as a result of auto inoculation

Course and Prognosis—These depend on the cause and the ease or difficulty of its removal With itching due to infestations it is easy with itching due to emotional conflict, it may be extremely difficult A carbuncle in a debilitated patient is a serious and sometimes fatal condition

Diagnosis—A boil or carbuncle has to be diagnosed from a malignant pustule (anthrax) In the latter, the onset is more rapid and the constitutional symptoms are more marked while the history of exposure to wool or hides makes the diagnosis likely Culture or even a direct smear will usually reveal the bacilli but treatment should be started on clinical grounds alone, without awaiting cultural confirmation

The primary tuberculous complex resembles an indolent boil but the youth of the sufferer a history of contact the lymphadenopathy draining the site of inoculation and the resistance to antistaphylococcal measures should arouse suspicion

Treatment—In every case the cause should be looked for and treated if possible Glycosuria or albuminuria malnutrition or leukæmia should all be excluded If *itching preceded the boils this should be investigated Occupational* hazard unsuitable clothing and faulty hygiene practices should receive attention

Severe boils and carbuncles are best dealt with by systemic penicillin or some other suitable antibiotic depending on organismal sensitivity tests Smaller lesions are better treated by local remedies Penicillin injections are a passive treatment having no value for stimulating the reactivity of the host in fact the converse sometimes applies, penicillin injections being followed on cessation, by a crop of further boils of even greater severity For this reason it is a mistake to give penicillin at once without first investigating the cause of the infection and the susceptibility of the organisms to antibiotics Vaccines staphylococcal toxoid manganese injections and tin by mouth have a reputation for relieving furunculosis but their effects are most uncertain

Local treatment should aim at resolution of the lesions with minimal discomfort and with the avoidance of further contamination of the skin by the pus coming from the boils Softening or maceration of the skin must be avoided and boracic fomentations kaolin poultices and glycerin and magnesium sulphate dressings often do more harm than good Dry heat may be applied with precautions to prevent burning or hot bathing may be used In the intervals between such procedures the following paint may be applied to and around the boil to control the local infection and to keep the surface of the skin dry and hard

Mercuric chloride	0 1 per cent
Brilliant green	1 0 per cent
75 per cent industrial spirit to	100 0 per cent

Once the boil is discharging dry dressings, frequently changed are used and chlortetracycline cream 1 per cent or the above mentioned paint, applied to the skin around

Surgery in particular crucial incisions is contraindicated and the only justifiable

TINEA CAPITIS (TINEA TONSURANS)

MICROSPOROSIS

Ringworm of the scalp in over 90 per cent of cases is due to microsporon either *Microsporon audouini* (the human form) or *M canis vel felineum* A much rarer form acquired from animals is *M gypseum* All forms only infect children the skin at puberty acquiring fungistatic properties

Ætiology and Pathology —The human form is believed to be spread by direct contact and by indirect contacts for example hair clippers and caps it may also be air borne The animal form is acquired by fondling kittens and puppies and may spread from child to child for two or three transferences before it loses its vitality which is re established after infection of an animal host once more

The organisms invade the stratum corneum and the mycelium grows down the hair follicles and thence passes to the hair shafts forming a mosaic of spores around the shafts and mycelial threads within the shafts The hair shafts become fibrillated and break off about 3 mm above the surface of the skin

Clinical Picture —As a general rule *M audouini* causes less severe reactions than *M canis* and is less likely to be associated with tinea of the glabrous skin The *history of animal contacts in the latter and of a school or institutional epidemic in* the former may also help to suggest the nature of the fungus

Characteristically there are circular areas of short bent or broken hairs with frayed ends and having thicker shafts than those of the unaffected scalp around The scalp itself shows a dirty scaling without redness or there may be slight papulo pustulation Rarely there are numerous follicular pustules with much œdema causing a boggy dusky dome shaped swelling a condition known as kerion This is more common with Trichophyton infections

Sometimes the circular or annular arrangement is inconspicuous or absent and casual inspection may suggest a diagnosis of infective dermatitis if the whole or most of the scalp is affected until closer inspection shows broken hairs which are not found in infective dermatitis

Examination with Wood s light is an invaluable aid to the diagnosis and management of these disorders It consists of ultra violet rays passed through a nickel glass filter With microsporon but not with trichophyton there is a brilliant green fluorescence of the affected hairs As the infection persists the fluorescence tends to become less brilliant With Wood s light the diagnosis can be made of microsporon ringworm affected hairs can more easily be removed for microscopy and culture and the follow up of patients until cure is greatly facilitated It is often noted under the lamp that single outlying hairs are affected and even that small patches are present which were not suspected on examination by daylight Direct microscopy is not essential if examination under Wood s light is positive It is carried out by extracting a hair and placing it on a slide with potassium hydroxide Heat is applied to hasten the keratolytic action of the potassium hydroxide Microscopy then reveals a mosaic of small spores surrounding the hair shaft

Diagnosis has now reached the stage of microsporosis Further differentiation is made by culture using Sabouraud s medium Usually the macroscopic and microscopic features of the culture are characteristic but occasionally dysgonic forms are seen

Course and Prognosis —The *natural history differs in the two types of infection M audouini* tends to persist indefinitely or until puberty whereas *M canis* usually dies out after about 3 months It follows that local applications may be sufficient in the latter but not in the former

Diagnosis —Alopecia areata causes smooth bald patches with exclamation mark hairs at the periphery Trichotillomania causes areas of broken off hairs usually at one temporo frontal region Infective dermatitis causes redness and scaling and

ERYSIPELAS (see p 34)

ERYSIPELOID

An infection of the cellular tissues of the fingers or hands with the organisms of swine erysipelas, from injury to the skin arising from the handling of animal or vegetable matter

Clinical Picture—This is essentially a disease of food handlers and manipulators It starts as an erysipelas like swelling on a finger or the hand The swelling advances with an easily visible border and may travel up one finger on to the hand and down the adjoining finger Constitutional disturbance is slight If untreated the condition persists for several weeks

Treatment—It quickly responds to intramuscular injections of penicillin

ANTHRAX

This is dealt with elsewhere (see p 79)

CUTANEOUS DIPHTHERIA

This is rare Wounds (for example desert sores) may be infected and occasionally lesions develop on the skin of children suffering from naso pharyngeal diphtheria The skin may also be affected without mucosal involvement

Clinical Picture—There may be only one lesion or several At first there is a blister which ruptures, a red zone develops around and a central slough forms Diphtheria may cause paronychia Constitutional symptoms are often slight but *the complications serious*

Diagnosis is from infected eczema, impetigo and ecthyma Direct smear and cultural examination for *Corynebacterium diphtheriæ* confirms the suspicion

Treatment—Diphtheria antitoxin should be given in full dosage immediately the condition is suspected *without waiting for a bacteriological report* The patient should be kept at rest and isolation is necessary Locally the area should be cleaned with cetrimide 1 per cent and an antibiotic such as chloramphenicol cream applied

FUNGOUS INFECTIONS

Mycotic infections of the skin may be superficial (epidermal) or deep (dermal) The former type is common, the latter rare

SUPERFICIAL FUNGOUS INFECTIONS

Pathogenic fungi are classified according to their morphological and cultural characteristics macroscopically and microscopically into *Microsporon*, *Trichophyton*, *Epidermophyton* For the clinician it is more convenient to classify fungous diseases according to the region of the body they are affecting The chief groups are *tinea capitis tinea barbæ tinea glabrosa tinea axillæ et cruris tinea pedis* and *tinea unguium* Two or more regions on one patient can be affected by a fungus concurrently, the zonal terminology being arbitrary For example *Trichophyton rubrum* may affect the nails the hands the feet and the groins at one time

Fungous eruptions particularly if infected with cocci or if over treated often give rise to secondary eruptions or mycides which depending on the nature of the fungus are described as microsporides trichophytides epidermophytides, favides or moniliides (levurides)

Favus may also affect the glabrous skin with scutuliform lesions in which bright yellow cups form massive crusts and it may cause nail deformity Favus is usually acquired in childhood but it persists into adult life if untreated

Treatment of scalp trichophyta depends on their natures With the animal ectothrix kerionic forms manual epilation followed by the application of Whitfield s ointment or magenta paint usually suffices It is wise to give warning of the probability of some degree of scarring The boggy swelling of kerion should not be incised

In the endothrix forms X ray epilation is usually necessary With favus it is important to examine all child contacts under Wood s light to find if any clinically undetectable early cases exist

TINEA BARBÆ

Ringworm of the beard is nearly always caused by *T mentagrophytes* or *T discoides* infections of animal source hence it is found mostly amongst grooms and farm workers It presents as irregular areas of follicular papulo pustulation in the beard area, with considerable perifollicular swelling which gives rise to the fig like nodular appearance of mycotic sycosis Microscopy of an extracted hair often fails to reveal the fungus because of a secondary coccal infection as in kerion celsi

Treatment is by manual epilation and the use of fungistatics for example Whitfield s ointment or Castellani s paint X ray exposures of 150 r up to four times at weekly intervals may be used to diminish the swelling and tendency to keloid formation

TINEA GLABROSA

Tinea of the glabrous skin may be classified for clinical purposes as tinea circinata of body and limbs tinea axillæ et cruris and tinea pedis

TINEA CIRCINATA

This form of ringworm affects children or adults and may be due to microsporon or trichophyton The former may occur in children with tinea capitis due to *M canis* or in adults coming into contact with them The latter may be of human or animal source In nearly all forms the infection spreads peripherally and heals centrally with the result that the early macular or papulo vesicular lesion becomes a ring with a scaly or vesicular border and a central zone of normal or discoloured skin In infections by *T discoides* (cattle ringworm) groups of papulo pustules occur on the forearms or on the backs of the hands but the endothrix trichophytons tend to form large rings

Diagnosis is from pityriasis rosea patchy infective (seborrhoeic) dermatitis nummular eczema

Pityriasis rosea begins with a herald patch followed by a general eruption but microscopy reveals no fungus

Discoid infective dermatitis has greasy scales a sweat area distribution and signs of infective dermatitis elsewhere

Nummular eczema presents with papulo vesicular disks on the forearms and hands calves and feet

Treatment.—Tinea circinata is usually eliminated easily with fungistatic agents such as Whitfield s ointment, magenta paint or weak tincture of iodine If the patient is a child it is important to examine the scalp under Wood s light even in the absence of clinical evidence of involvement of the scalp

In the pustular form it is advisable to carry out manual removal of any hairs present.

loss of hair but no *breaking of the hairs Impetigo of the scalp is* more exuberant and lesions are usually present elsewhere, or there is some other cause for it such as pediculosis

Treatment —Scalp ringworm is a problem in epidemiology With *M audouini* it is necessary to examine the contacts and to trace the infection to its source if possible A Wood s light is invaluable for this purpose In residential institutions tracing the source and quelling the infection is relatively simple In day schools it may be difficult because *siblings of all the school contacts should be examined as well* Fortunately as microsporosis is almost unknown after puberty, it is not necessary to examine children over 14 years of age

Treatment should be begun with local applications pending the cultural diagnosis The choice of local application is, at present relatively unimportant as one is not available which will eliminate the infection from the depths of follicles and from the hair shafts themselves which is the essential of cure Local applications serve the purpose of fungistatic action on the surface and at the ostia and prevent contaminated fragments of scale or hair from being carried off in the air

The mother is instructed to cut the hair all over the head to stubble and to make two linen closely fitting skull caps for continual wear, on alternate days, the cap not in use being boiled The scalp is scrubbed daily with soap and water paying special attention to the areas known to be affected Then the ointment being used (Whitfield s ointment or phenyl mercuric nitrate 0 5 per cent in emulsifying ointment or dithranol 0 5 per cent in emulsifying ointment) is scrubbed into the scalp with enough vigour to cause a slight erythematous reaction

In small spore ringworm of the scalp due to *M audouini* it is exceptional to get a cure with local applications and recourse is had to X ray epilation using either a *4 or a 5 circular fields method The hair falls after 3 weeks when examination* under Wood s light will reveal any affected hairs that may remain These can be removed gently with epilation forceps In the epilating stage a fungistatic ointment, for example Whitfield s should be applied and the falling hair burned Epilation by *thallium acetate (8 mg per kg of body weight) in a single dose is too dangerous* a method and has been practically abandoned death having occurred from accidental overdosage

RARER FORMS OF SCALP RINGWORM

Large spore ringworms of various types may affect the scalp They include two *forms contracted from animals T mentagrophytes from domestic or* farm animals and *T discoides* from cattle Both are ectothrix forms In the former filaments and spores are seen around the hairs in the latter large spores Four endothrix forms all of human origin include *T tonsurans*, *T sulphureum T violaceum* and *T schoenleini* (favus) None of these forms of scalp ringworm causes fluorescence under Wood s light, except favus which gives a pale bluish green fluorescence throughout the length of the hairs which often remain unbroken

Microscopically the endothrix ringworms show filaments and spores within the hair shafts Favus may be recognisable at this stage by its polymorphic filaments and oval spores with areas having the appearance of air spaces within the shafts

Clinically the trichophyta of animal origin usually cause kerion but the endothrix *forms cause much less violent reactions* perhaps some scattered broken hairs with thick scurf with *T violaceum* the hairs break off flush with the surface of the skin (black dot ringworm) giving an appearance that can easily be confused with alopecia areata Microscopy after careful removal of a hair reveals the fungus as mycelial threads and oval segments Favus may resemble infective dermatitis mousey smelling, yellow scutuliform scales may be present or in long standing cases where the scalp has been kept clean it may present as a slowly extending cicatricial alopecia

changed daily or a fresh pair of white cotton in socks can be worn each day Sponge rubber soles should not be worn The feet should be washed twice a day and magenta paint applied at night and 3 per cent salicylic acid powder liberally shaken into the socks and between the toes each morning Mercurial fungicides are liable to sensitise the skin and zinc undecylenate is relatively ineffective Whitfield s ointment is some times useful or 1 per cent silver nitrate lotion If any secondary infection is present foot soaks in potassium permanganate 1 in 6000 for 10 minutes twice a day are useful

TINEA UNGUIUM

Ringworm of the nails may be due to trichophyton or epidermophyton It may pick out one nail one hand or foot or both It is unusual for all the nails to be affected and the distribution is usually asymmetrical

Clinical Picture —The nails are usually affected from their free edges and become grey or brown thickened rough dull friable and honeycomb like They are sometimes easily shed To make a microscopic examination for fungus a micro scope slide is used by scraping with its edge fine flakes of nail can be detached The more superficial ones are discarded the deeper ones are caught on another slide covered with potassium hydroxide and a cover slip and heated to hasten the keratolytic action of the potassium hydroxide It is usually easy to find mycelium by this method but subsequent attempts at culture often fail

Diagnosis —Ringworm of the nails has to be differentiated from psoriasis eczema syphilis and nail dystrophies Psoriasis usually affects many nails in sym metrical fashion Thimble like pitting may be present or the nails may be thickened and yellow In tinea unguium there may be only one or two nails affected and the discoloration is dirty grey rather than yellow Microscopic examination for mycelial filaments is the deciding method in doubtful cases in addition to the presence or absence of psoriasis or fungous disease elsewhere Paronychia is rarely caused by pathogenic fungi but often in part due to monilial infection

Treatment —The eradication of fungous infections of the nails is very difficult and success is exceptional Removal of the nail plates and the application of fungi cides to the nail bed is usually followed by recurrence X ray exposures and thorium X applications have sometimes been reported to give partial success Useful local applications include ammoniated silver nitrate $\frac{1}{2}$ per cent dithranol ointment and zinc undecylenate ointment but the most that can be said for each and all of these is that they may help to check the spread of the disease on the sufferer and to others It is important to treat concurrently any skin areas involved

MONILIAL INFECTIONS

Monilia (candida) albicans may affect the mucosæ and skin in several ways monilial stomatitis (thrush) monilial vulvovaginitis monilial intertriginous dermatitis monilial paronychia

Monilial stomatitis occurs as thrush in infants with white easily detached shreds overlying the mucosæ In adults monilial stomatitis may follow the use of anti biotics which disturb the flora of the mouth

Angular stomatitis is sometimes infected with monilia

Monilial vulvovaginitis is a cause of pruritus vulvæ and usually presents as a shiny flexural erythema with a heaping up of white sodden epidermis at the margin

Monilial flexural dermatitis has a similar appearance at other sites chiefly under pendulous breasts or abdominal folds at the umbilicus at axillary and genitocrural flexures and between the fingers in the form known as *erosio interdigitalis mycotica* It is a common cause of sodden skin in the toe clefts

In all these forms of monilial dermatitis it is important to test the urine for sugar and to look for evidence of nutritional deficiency

TINEA AXILLARIS ET CRURIS

This presents as extensive areas of erythema in the *flexures with festooned poly cyclic* edges showing some scaliness or slight vesiculation from which mycelium can be recovered The anal region, the perineum, the scrotum and the buttocks may *be affected as well as the genito crural folds* The responsible organism is usually either *T rubrum* or *Epidermophyton floccosum* either may also affect the hands feet and nails but *E floccosum* does not affect the hair

Diagnosis —In infective dermatitis of the flexures there are numerous follicular erythematous "satellite' lesions In ringworm of the axillæ and groins (eczema marginatum) *these are not present In doubtful cases microscopy should make the* diagnosis clear In flexural dermatitis due to hæmolytic streptococci the intensity of inflammation is much greater and in monilial dermatitis the white sodden epidermis overlying the moist, reddened surface with fissuring in the depths of the folds makes the diagnosis clear Contact dermatitis due to textiles is recognised by its preference for the folds of the axillæ rather than their domes

TINEA PEDIS

This is usually due to *T mentagrophytes*, *T rubrum* or *F floccosum* Cultural differentiation is important because eradication of *T rubrum* is a far more difficult *matter than eradication of T mentagrophytes* or *E floccosum*

Ætiology —Foot ringworm is most easily spread where people mix in bare feet hence its designation 'Athlete s Foot Sports clubs swimming baths and bath rooms are probably the commonest sources of contagion but individual susceptibility because of hyperidrosis crowded toes and minor foot deformities is also important *Other factors include climatic and working conditions of heat and humidity* and faulty footwear, in particular thick socks and impervious footwear

Clinical Picture —On the inner surface of the foot spreading on to the sole, groups of vesicles are present of various sizes and of skin colour Secondary *infec* tion may cause opalescence of the vesicles The eruption is usually somewhat asym- metrical Other parts of the sole may be infected especially the flexures and clefts of the toes but when the only physical sign is white sodden skin with fissuring of the fourth toe clefts monilial intertriginous dermatitis is a more likely diagnosis

In the presence of secondary infection or over treatment a secondary eruption (mycide) of vesicles often develops symmetrically on the hands and feet These vesicles do not contain fungus and the hand condition is in no way contagious Infec tion may however spread to the nails of hands and feet

T rubrum infections behave in a different fashion It is not unusual to find simultaneous infection of the hands feet nails and groins The hands and feet usually show a diffuse fine peeling and some redness only perhaps with hyperkera tosis and fissuring but without vesiculation often the condition is unilateral One *or more nails may be affected as well* On the calves there may be discrete deep follicular lesions resembling a deep coccal folliculitis tuberculide or even erythema nodosum

Diagnosis —Microscopic confirmation by *removing the roofs of suspected* vesicles is essential if errors are to be avoided as a very similar if not identical picture can arise in pompholyx (dysidrosis) and in contact dermatitis Contact eczematous dermatitis of the feet usually arises on the dorsa but may itself be due to over treat ment of tinea pedis Tinea pedis is often asymmetrical whereas pompholyx is sym metrical Sodden toe clefts may be due to excessive sweating and maceration or to monilial infection

Pustular psoriasis of the feet presents as reddened areas with excessive scaling and brown pustules ' *which are sterile on culture* and microscopically show no fungus

Treatment —Footwear should be well fitting socks should be of cotton and

Treatment consists of shaving followed by the application of calamine lotion with 2 per cent of sulphur

MYCIDES

These may take the form of vesiculation of the hands (pompholyx) or lichenoid horny follicular papules in groups on the trunk (lichen trichophytide) Erythematous urticarial erythema multiforme and erythema nodosum types have been described

Treatment is by bland local applications while the primary focus is being got under control

DEEP FUNGOUS INFECTIONS

These conditions are rare in Great Britain

SPOROTRICHOSIS

This is caused by accidental inoculation with *Sporotrichum schencki* a plant sapro phyte Infection usually takes place through the hand or forearm and vegetable handlers or persons attending to animals are most likely to be affected There is a primary lesion at the portal of entry an ascending lymphangitis and chains of nodules which break down and suppurate along the course of the lymphatics

Clinical Picture —There may be cutaneous mucosal or systemic manifestations There may be a chancre like lesion with lymphangitis and lymphaden tis and multiple subcutaneous cold abscesses which break down to form gummatous or ecthymatous ulcers with little or no pain Apart from the skin cold abscesses may form in the mucosæ muscles lymph nodes joints bones epididymis lungs gastro intestinal tract or the central nervous system

Diagnosis is from late syphilis halogen eruptions other fungous infections and the primary tuberculous complex The lymphatic spread is typical of sporotrichosis Syphilitic gummata are usually single or few in number The primary tuberculous complex has a portal of entry and an ulcerated lymph node draining it but not chains of ulcers along the lymphatics as in sporotrichosis Halogen eruptions may be granulomatous and ulcerative but are usually symmetrical and do not have a distribu tion corresponding to a lymph drainage area In sporotrichosis there are multiple lesions in lymphatic distribution with little constitutional disturbance

Treatment —Potassium iodide in ascending dosage up to the limits of toleration usually brings about a steady resolution

BLASTOMYCOSIS (GILCHRIST S DISEASE)

In the localised form of this infection with *Blastomyces dermatidis* papulo-pustulation goes on to the formation of large ulcers bordered by papillomatous vege tations and with discharging sinuses and epidermal bridges The proliferation of the epidermis may be so marked as to resemble epithelioma (pseudo epitheliomatous hyperplasia) In the systemic form the lungs are most commonly affected but no organ is immune

Course and Prognosis —The condition is benign but chronic

Diagnosis is from syphilis sporotrichosis halogen granulomata vegetating pyo derma tuberculosis verrucosa cutis and epithelioma Repeated microscopic and cultural search may be necessary before the budding yeast fungus is demonstrated The histology resembles tuberculosis but with blastomyces in the centre of a nodule

Treatment is by thorough curettage and cautery of the extending hyperplastic edge X ray therapy is usually ineffective Potassium iodide in large doses should be given a trial

Monilial paronychia—The cause of chronic paronychia is a break in the epidermal barrier due to the effects of alkalis, detergents cuticle removers or excessive manicuring Once this barrier is broken down *Staphylococcus saprophyticus* and yeasts gain access to the folds and cause a low grade inflammation If the hands are repeatedly immersed in alkaline solutions or if they are exposed to beer as with barmaids cleaning up bar counters conditions are rendered ideal for the infection to develop

Treatment of monilial infections consists of attention to the general health, attention to the local anatomical condition predisposing to this infection and the application of fungicides

Unbalanced nutrition obesity and any associated diabetes must be controlled Opposing skin folds should be prevented from rubbing against one another by means of suitable dressings up lift brassieres and abdominal supports well fitting socks and shoes The affected areas should be kept clean with an unscented toilet soap and after its use a talcum dusting powder should be liberally applied to the less active areas and magenta paint to the more active ones To any fissures in the depths of the folds a 2 per cent solution of silver nitrate applied daily by an orange stick is usually effective

Monilial paronychia can only be relieved with full co operation on the patient s part Wet work must be kept to a minimum and the handling of soda, alkaline soaps and detergents is forbidden Magenta paint is allowed to trickle under the nail folds by means of a camel hair brush X ray exposures to the folds (150 r) weekly or fortnightly on up to four occasions are often invaluable in encouraging the re growth of the epidermis over the proximal parts of the nail plates After cure the patient must be reminded of the possibility of recurrence and advised to take especial care to avoid the known hazards

TINEA VERSICOLOR

Malassezia (microsporon) furfur is the organism responsible for this condition which presents as brown, slightly scaly plaques on the body and to a lesser degree on the limbs If the skin has been exposed to sunlight the affected areas may be paler than the normal areas adjoining (achromia parasitica) The affected areas are also pale in coloured people

Diagnosis—In tinea versicolor in the white man the brown areas are ' islands in a ' sea of white and the edges of the brown are convex In vitiligo the converse applies In tinea versicolor there is slight scaling made more apparent by scraping the edge of brown Microscopic examination of these scales reveals fragments of mycelium and many spores sometimes in clusters resembling bunches of grapes This fungus will not grow on artificial media Another diagnostic feature is a golden fluorescence when the patient is examined under Wood s light

Treatment—Tinea versicolor is encouraged by hyperidrosis or sweat retention hence it is wise to look for any tuberculous or other condition which might be responsible for the sweating Insufficient bathing and the wearing of the same thick woollen underclothing day and night may be to blame Bad habits of this sort must be corrected and porous underclothing worn and changed daily if the condition is to be cured The application of 10 per cent sodium thiosulphate is effective or the 3 per cent ointment of sulphur and salicylic acid may be applied Treatment should be continued for 2 weeks after apparent cure The bed linen and underclothes should be disinfected by laundering

LEPOTHRIX (TRICHO MYCOSIS AXILLARIS)

This is a fungous infection around hairs in the axillæ producing dark reddish concretions and caused by *Nocardia tenuis* in symbiosis with a coccus which forms red yellow or black pigment

Inoculation through the skin may happen when contaminated dust is accidentally abraded into the skin as when an infant crawls on the floor in a house in which there is a patient with open pulmonary tuberculosis Lupus most commonly begins in the first decade but occasionally starts much later in life The face particularly around the orifices is the commonest site of infection but the elbows hands knees buttocks and perianal region are other relatively common sites Local spread then proceeds by the lymphatic channels or these vessels may be the route by which an infection primarily infecting the nose reaches the skin Involvement of the skin by spread from underlying tuberculous foci takes place in scrofuloderma (King s Evil) from the breaking down of cervical tuberculous lymph nodes also from sinuses draining tuberculous kidneys bones and joints Spread by the blood stream only occurs in states of extreme debility which may arise with measles or pertussis In this form multiple foci may occur on widely separated parts of the skin In its extreme form of severity blood dissemination causes the rare and often fatal condition of tuberculosis cutis miliaris acuta or lupus miliaris in which the multiple miliary areas of tuberculosis are only the outward signs of a miliary tuberculosis of internal organs

Typical tubercles are seen in the dermis with round cells surrounding a zone of epithelioid and giant cell histiocytes There is considerable disruption of collagen with a variable amount of fibrous tissue formation Secondary epidermal changes may include atrophy and a patchy parakeratosis but at some sites for example the hands and buttocks warty thickening may occur (lupus verrucosus)

Clinical Picture —The nodule of lupus vulgaris is a flat semitranslucent area with slight scaling—the apple jelly' nodule described by Jonathan Hutchinson Subsequently the lesion may have exudative or fibrotic characters In the former there is some swelling and redness and no tendency to heal spontaneously ulceration may occur In the fibrotic form the lesions are not raised and ulceration does not occur but the lesions tend to heal in places with much scarring only to break out once more here or elsewhere As a result multiple foci of activity may remain amongst extensive areas of scarring

Lupus around the nose and mouth is often complicated by mucosal lupus in the nose or on the gums cheek tongue palate pharynx or larynx Mucosal lesions are different from the cutaneous ones being dusky granular infiltrations which bleed easily

Lupus vulgaris may destroy cartilage but not bone The resultant deformities that may arise include simian or parrot bill deformities of the nose due to destruction of the alæ and septum respectively septal perforation and stenosis or occlusion of the anterior nares The mouth may be narrowed by scarring (microstomia) or the upper lip may be retracted permanently exposing the gums Contracture of scarring below the eye often causes ectropion The pinnæ may be destroyed irregularly or completely or they may as a result of the inflammatory process become adherent to the skull Some of these deformities are in part due to secondary infection or to the use of caustics and X rays in treatment Lesions on the limbs and body may be very extensive Ulceration may be followed by scarring and contractures or lymphatic obstruction may lead to elephantiasis

Complications of lupus include secondary infection particularly in the nose contractures elephantiasis and the development of keratoses and prickle cell carcinoma This is particularly likely to happen in patients who have received X ray treatment for the lupus but it may also occur in patients who have had much treatment by ultra violet irradiation and other locally destructive procedures

Lupus vulgaris may be associated with phlyctenular keratitis tuberculosis of the upper respiratory tract of bones joints or kidneys and rarely of the lungs

Diagnosis —The earliest lesions may resemble moles but on diascopy (inspec tion through a piece of glass firmly applied to the skin) it is clear that the brown colour is due to an exudative process and of apple jelly appearance whereas with moles and

ACTINOMYCOSIS

This condition is due to bacteria like fungi of genera Nocardia Actinomyces or Streptothrix The cutaneous form (cervico facial) causes dermal infiltration leading to indurated irregular subcutaneous nodulation going on to ulceration, with sinuses from which seropurulent or sanguineous fluid containing sulphur yellow granules is discharged Further nodules form nearby with boardlike hardness The skin may also be involved secondarily from deeper involvement in the mouth thorax or abdomen The tongue lungs, intestines, urinary tract female genitalia or bones may be affected

Histology—A granule consists of one or more colonies each of which has mycel lium and pigment granules in the central zone and club shaped organisms in palisade arrangement at the periphery The branching hyphæ are Gram positive

Course and Prognosis—The course is slow, the malady sometimes persisting for up to 10 years

Diagnosis from syphilis sporotrichosis scrofuloderma and carcinoma is made from a consideration of the clinical bacteriological and histological findings (*q v*)

Treatment is by penicillin or other antibiotic Surgery and X irradiation may also be of value

CUTANEOUS TUBERCULOSIS

The skin may be invaded by tubercle bacilli or it may be the site of reactions of hypersensitivity to these organisms (tuberculides) When the skin is invaded by tubercle bacilli its manner of response depends on the immunological state of the host at the time If the individual has suffered no previous tuberculous infection at any site the Mantoux reaction is negative (primary anergy) and the response will be the primary tuberculous complex but if there has been a previous tuberculous infection in the skin or elsewhere, and the Mantoux reaction is positive the response will be lupus vulgaris (normergy) It is believed that if a secondary anergy develops any subsequent tuberculous infection causes the condition known as sarcoidosis, although this reaction may also be non tuberculous Some individuals develop an excessive sensitivity to tuberculin In them tuberculous infection at any site may be followed by some form of tuberculide (hyperergy)

THE PRIMARY TUBERCULOUS COMPLEX IN THE SKIN

This consists of a tuberculous chancre on some exposed part of the body such as the face eye hands or knees and enlargement of the lymph node draining the area The chancre resembles a boil but instead of suppurating it persists as a crusted indurated patch with a little bloodstained discharge The lymph node draining the site enlarges softens and breaks down through the skin leaving an irregular scar Subsequently the primary chancre slowly heals up or it may form the focus from which a patch of lupus vulgaris develops The Mantoux reaction changes from nega tive to positive with the development of the primary complex

Diagnosis has to be made from a low grade coccal infection

LUPUS VULGARIS

Ætiology and Pathology—Infection of the skin causing lupus vulgaris may take place by inoculation by lymphatic spread by the breaking down of some under lying tuberculous focus or by the blood stream Either human or bovine bacilli may be responsible

effect as well as helping by the formation of vitamin D in the skin Light treatment still has its uses to day when dealing with solitary resistant foci for which a course of isoniazid may be considered unjustifiable

LUPUS VERRUCOSUS (TUBERCULOSIS VERRUCOSA CUTIS)

This is usually due to inoculation from without It most commonly occurs on the hands or buttocks as a violaceous warty excrescence with a reddish halo and a sero purulent discharge One form of it is the verruca necrogenica the anatomical tubercle or post mortem wart acquired from a human or bovine cadaver but the infection can also occur from a patient s own tuberculous sputum The lesions may be secondarily infected but they do not ulcerate Dissemination of tubercle bacilli may occur from them through the lymphatics to lymph nodes and the blood stream The histological appearance is of a nonspecific inflammatory reaction with overlying papillomatosis or there may be a tuberculoid appearance

Diagnosis is from warts lichen planus verrucosus syphilis vegetating pyoderma and blastomycosis Warts do not show dusky discoloration Lichen planus verru cosus usually occurs on the shins or on the forearms and itches intensely Syphilis is much more actively inflammatory than the indolent lupus verrucosus Vegetating pyoderma and blastomycosis can only be differentiated by histological and cultural methods

Treatment is by surgical excision curettage and cautery or by oral treatment with isoniazid

TUBERCULOSIS COLLIQUATIVA (SCROFULODERMA)

This is tuberculosis of the skin secondary to tuberculosis of underlying lymph nodes joints or bones

Clinical Picture —The commonest form is in the neck secondary to tuberculous cervical adenitis Subcutaneous nodules become attached to the skin which becomes dusky and indurated finally the mass breaks down and a crusted sinus is exposed or ragged undermined ulcers form with intercommunicating sinuses When the condition heals irregular scarring is left

Diagnosis from syphilis actinomycosis and sporotrichosis is on clinical grounds and by cultural serological and histological methods

Treatment is by attention to good feeding housing and fresh air general ultra violet irradiation and isoniazid by mouth 300 to 400 mg daily Surgical intervention is sometimes necessary

TUBERCULOSIS CUTIS ORIFICIALIS

This is a form of painful tuberculous ulceration in or around the orifices usually secondary to tuberculosis of internal organs thus tuberculous ulcers of the nose palate tongue floor of mouth or the lips arise from infection by sputum from a pul monary or laryngeal focus ulceration of the external genitalia in both sexes may occur from tuberculosis of the genital or urinary tracts Perianal ulcers may occur in persons with intestinal tuberculosis The ulcers are painful shallow and ragged with undermined edges and dirty grey bases from which there is a mucopurulent secretion

Diagnosis is from chancre epithelioma or chancroid by bacteriological examina tion from the base of the ulcer

Treatment is by electro cautery or chemical cautery with acid nitrate of mercury and with isoniazid by mouth

TUBERCULIDES

These are skin reactions which are due to hypersensitivity (hyperergy) to tuber culin In some forms this relationship is clearly established in others it is suspected but not proven

freckles it is duller and without translucency More advanced lesions have to be differentiated from syphilis, tuberculoid leprosy sarcoidosis, lupus erythematosus lupoid sycosis and rodent ulcers Lupus vulgaris usually starts in the first decade affects skin and cartilage and takes years to develop, showing characteristic apple jelly nodules Syphilitic gummata develop much more rapidly, usually in the 30 to 50 age group and may ulcerate and destroy in weeks or months to an extent that would take lupus several years Bone may be destroyed as well as cartilage and skin and it is not unusual for a gumma to form deeply and to ulcerate rapidly with the formation of a large cavity perhaps involving the maxilla Tuberculoid leprosy may closely *mimic lupus but there is anæsthesia* to light touch, and heat and cold, the nerves in the area may be thickened and tender and the patient has lived in an area of endemic leprosy

Sarcoidosis presents as raised, pinkish yellow, translucent nodules about the face or on the shoulders and arms, or as indurated erythematous lesions on the legs Histological study may be necessary in the differentiation

Lupus erythematosus is often symmetrical and involves the "bat's wing' area of the face, the scalp (which is seldom affected by lupus vulgaris) the vermilion surface of the lips and perhaps the backs of the fingers There is redness with follicular plugging, scaling and central atrophic scarring but without apple jelly nodulation A very important differential point from lupus vulgaris is that lupus erythematosus never involves cartilage so that no matter how long it has been present there is no serious deformity of nose or ears and no loss of tissue other than the skin

Rodent ulcer may be simulated by ulcerated lupus but it has a hard pearly edge, whereas ulcerated lupus is ragged Lupus vulgaris may be complicated by squamous cell epithelioma

Ancillary aids to differential diagnosis include biopsy, the Wassermann reaction the *Mantoux reaction the Kveim test and the lepromin test*

Treatment of lupus has been revolutionised in the last few years Isoniazid in a dose of 300 to 400 mg a day leads to disappearance of the nodules and of scaling within 2 to 6 months almost without exception Time alone can tell of the permanency of this effect because with all treatments of lupus vulgaris 'cure can only be considered a possibility after 5 years uninterrupted clinical clearance In the present state of knowledge a course of 6 to 12 months seems necessary There is no evidence of the development of drug resistant organisms Toxic reactions are slight and rare Histologically the nodules gradually become nonspecific and finally disappear Under an *umbrella* of isoniazid it is *possible to day for the surgeon* to carry out plastic repairs with far greater confidence than in the past

Calciferol either by local injection (300 000 units once a fortnight) or orally (150 000 units daily) is also effective but in a different way The lesions at first become worse, redder and more swollen then become less conspicuous with much fibrosis Histologically the tubercles remain but they are surrounded by an increased fibroblastic and fibrotic reaction Toxicity is a far greater hazard with calciferol The urine should be tested fortnightly and blood urea estimations carried out If the blood urea rises above 70 mg per 100 ml it is advisable to suspend the treatment Early symptoms of intoxication are euphoria capricious appetite *vomiting diarrhœa* or constipation headaches and vertigo

The general health domestic and occupational surroundings and nutrition of the lupus patient should always receive attention The diet should include ample milk butter and eggs Coexistent tuberculosis in other organs is not uncommon particularly in lymph nodes bones joints and kidneys rarely in the lungs

Before the introduction of calciferol and isoniazid the local treatment of lupus vulgaris mainly consisted of destructive measures with the Finsen Lomholt lamp, the Kromayer lamp and by chemical caustics such as the acid nitrate of mercury General ultra violet irradiation is also valuable *It has an unexplained* tonic

ACNE SCROFULOSORUM

This also affects children and adolescents who have some form of tuberculosis elsewhere The lesions especially appear on the buttocks and thighs they are red acuminate follicular papules and pustules The Mantoux reaction is positive

Diagnosis from staphylococcal folliculitis is by the more prolonged course of the tuberculous lesions and their lack of response to antibiotics

Treatment is of the primary condition and general measures to raise the resistance

PAPULONECROTIC TUBERCULIDES

Papulonecrotic tuberculides have various forms and distributions some are truly tuberculous but others may in fact be virides Superficial forms have been called follicles deeper ones acnitis Papulonecrotic tuberculides of the extremities consist of discrete inflamed papules which undergo central necrosis ulcerate form scabs and heal with scarring They occur on the extensor aspects of the forearms and legs and on the backs of the hands and feet The whole process may take some 8 weeks but there may be successive crops The Mantoux reaction may be normergic or hypoergic.

Lupus miliaris disseminatus faciei consists of multiple pinhead sized flat, discrete semitranslucent lesions which occur symmetrically on the posterior halves of the cheeks They are probably tuberculous the Mantoux reaction being strongly positive

ACNE AGMINATA

This is a condition in which acneiform apple jelly like nodules occur on the nose eyelids and face often grouped together They may also occur on the genitalia After a variable persistence they may disappear with slight pock like scarring The Mantoux reaction is usually hypo or anergic and the condition is not proven to be tuberculous it may be of virus origin (see Acneiform Eruptions)

ROSACEOUS TUBERCULIDE OF LEWANDOWSKY

This condition of translucent pink papules on the forehead cheeks and chin resembles rosacea The Mantoux reaction is strongly positive It may be a tuberculide localised by a rosaceous circulation

Histopathology of the Tuberculides—All these lesions show a tuberculoid structure but this does not of necessity prove a tuberculous ætiology A tuberculoid structure is often seen in acne vulgaris and in rosacea

SARCOIDOSIS (BENIGN LYMPHOGRANULOMATOSIS)

This is an infiltrative and nodular disease affecting the skin and internal organs

Ætiology and Pathology—Controversy persists as to the cause of sarcoidosis It appears to be an unusual type of reaction to the tubercle bacillus but it may also occur in relationship to leprosy syphilis foreign bodies or beryllium The Mantoux reaction is negative an acquired anergy to tuberculin it is probable that this anergy is sometimes more general

Histologically there are naked tubercles well defined concentric aggregates of epithelioid cells without any necrosis or marked surrounding inflammatory reaction There may be a few giant cells Tubercle bacilli cannot be found In older nodules fibrosis predominates

Clinical Picture—Most patients are middle aged adults women more often than men There is often very little disturbance of general health but there may be slight pyrexia Sarcoidosis has extremely variable cutaneous manifestations There

ERYTHEMA NODOSUM

This is a nonspecific reaction of hypodermal vascular hypersensitivity one of the causes of which is a recently developed tuberculin hyperergy (see Erythema Nodosum)

ERYTHEMA INDURATUM

Erythema induratum or Bazin s disease is a condition of dusky, painful nodulation on the lower halves of the legs of young women with perniotic "billiard table legs A faulty peripheral circulation seems to predispose to this malady which is rarely, if ever seen in males or in women with an efficient peripheral circulation The indurated areas are painful and tender and may break down and form ragged ulcers with undermined edges secondary coccal infection may follow The malady is usually bilateral The Mantoux reaction may be hyperergic normergic or hypo ergic

Pathology—There is a heavy infiltrate in the hypoderm replacing the fat The infiltrate also involves the deeper parts of the dermis It may be specifically tuber culoid in some areas and nonspecific in others The vessels show marked proliferative changes and obliterative thromboses are seen Caseating necrosis may extend up wards from the hypoderm and lead to ulceration

Clinical Picture—The bluish calves show in their lower thirds on their postero medial and postero lateral aspects irregular hard dusky painful plaque like nodula tions which often necrose centrally and leave depressed scars There may be no other sign of tuberculosis or there may be a history of a pulmonary infection or of the presence of tuberculides elsewhere for example of the papulonecrotic variety

Course and Prognosis—The changes in the hypoderm are to some extent, irreversible, and some degree of scarring is inevitable

Diagnosis is from subcutaneous (Darier-Roussy) sarcoids erythema induratum of Whitfield and syphilitic gummata In sarcoidosis there are often other lesions elsewhere on the skin and ulceration is unusual In Whitfield s erythema induratum middle aged women are mostly affected and the lesions are multiple Syphilitic gummata are painless often single ham coloured serpiginous ' punched out ' ulcers

Treatment is by elastic supports good food, housing and fresh air general ultra violet irradiation (provided there is no pulmonary focus) and isoniazid 300 mg daily Calciferol is contraindicated It may cause rapid softening of the lesions and extensive ulceration or an outcrop of papulonecrotic tuberculides Ulcerated lesions may need appropriate antibiotics to control secondary infection apart from this they should be treated in the same way as hypostatic ulcers (*q v*)

LICHEN SCROFULOSORUM

This is a rare form of tuberculide consisting of lichenoid papules which usually occurs in children with tuberculous lymph nodes bones or joints

Clinical Picture—There are brownish red lichenoid follicular papules scattered or grouped in circles sometimes with a spiny tip slight scaling crusting or even pustulation The lesions mostly appear on the trunk and there is slight itching The Mantoux reaction is strongly positive

Diagnosis is from lichen planus This is rare in children and usually causes severe itching The lesions are violaceous polygonal papules with a waxy surface In doubtful cases the histology is diagnostic the papules of lichen scrofulosorum having a tuberculoid structure

Treatment is of the underlying tuberculous condition

Ætiology and Pathology —The cause is a delicately balanced host virus relation ship easily disturbed in favour of the virus Infection with herpes virus takes place in infancy and the immunological state that results usually prevents outbreaks of herpes except when there is a severe upper respiratory infection

Histologically there are intra epidermal unilocular or multilocular vesicles with swollen grossly degenerate epidermal cells

Clinical Picture —Outbreaks may occur occasionally with severe infections or frequently and from insignificant or even undetectable stimuli Precipitating causes include coryza slight pyrexia exposure to sunlight menstruation digestive upsets and emotional stimuli Genital herpes may occur after intercourse with one partner but not with another

The outbreak begins with the appearance of a group or groups of painless reddened papules rapidly becoming vesicular The lesions may be bilateral The vesicles may remain intact or rupture forming golden scabs on an erythematous base The lesions occur most commonly on the vermilion surface of the lips around the mouth or on the cheeks ears or nose they may occur on the buttocks or on the external genitalia There is no enlargement of the regional lymph nodes unless secondary infection occurs as is not unusual An associated oral aphthosis is un common

Uncomplicated lesions pass through their various stages and resolve in 10 to 14 days Recurrences may occur as often as once a fortnight or only very occasionally the lesions recurring at the original sites or nearby especially on the cheeks lips genitalia or buttocks

Course and Prognosis —The condition is not amenable to present methods of treatment and may recur indefinitely

Diagnosis is from zoster and from impetigo

Zoster is a nonrecurrent unilateral painful malady with enlargement of the regional lymph nodes The lesions conform to a posterior nerve root (or roots) distribution

Impetigo is characterised by golden stuck on crusts or by purulent blebs and usually there are other lesions on the face in the nostrils or at the paronychial folds This differential diagnosis is one of the most important and recurrent problems of dermatology the misdiagnosis of herpes simplex as impetigo often being followed by unsuitable treatment and the development of a contact eczematous dermatitis

Herpes preputialis forms shallow ulcers which do not enlarge This helps to differentiate them from syphilis and soft sore but a dark ground examination should be made in any suspicious circumstances

Treatment —There is at present no specific treatment for herpes simplex Precipitating factors should receive attention when discovered Local applications should be bland for example calamine liniment antibiotics are best avoided An individual attack can be shortened by a single X ray exposure of 100 r but this procedure should not be used except for some special occasion It has been claimed that repeated vaccination with calf lymph sometimes checks recurrences

ZOSTER (ZONA HERPES ZOSTER SHINGLES)

An eruption of vesicles in unilateral segmental distribution

Ætiology and Pathology —The cause is an infection of the posterior nerve roots and corresponding area of the skin with the virus of varicella The virus may be activated by infections neurosyphilis neoplasms Pott s disease of the spine Hodgkin s disease and other reticuloses certain drugs particularly arsenic or deep X irradiation but usually no such cause is apparent

Zoster may coincide with one or several vesicles of varicella elsewhere on the

may be raised, dome shaped nodules with an apple jelly appearance on diascopy or more deeply situated lesions causing purplish or skin coloured opaque nodules or plaques with fine vessels coursing over the surface The more superficial lesions (sarcoidosis of Boeck) appear especially on the nose cheeks lips shoulders and upper limbs The deeper lesions (Darier Roussy sarcoids) appear on the face and extensor aspects of the limbs including the sarcoid variant of erythema induratum on the legs Diffusely infiltrating erythrodermatous, annular and serpiginous forms of sarcoidosis are also described

In one form (lupus pernio of Besnier) the nose, ears hands and feet are dark blue, swollen and doughy but not cold Sarcoidosis may affect practically any organ in the body, causing mucosal lesions uveoparotitis hilar glandular enlargement or pulmonary infiltrations, enlargement of lymph nodes, tonsils, spleen liver, breasts testes, etc, disturbances of the gastro intestinal, genito urinary systems, peripheral or central nervous systems The iris and the choroid may be affected sometimes accompanied by swellings of salivary glands (uveoparotitis) Involvement of the bones of the hands or feet may cause absorption of bone and a radiographic picture of cyst like rarefactions Radiography may also show hilar glandular enlargement, radiating peribronchial infiltrations or a diffuse mottling

Course and Prognosis—Sarcoids may heal spontaneously or may steadily progress with increasing disability Sometimes tuberculosis develops the Mantoux reaction becomes positive and the sarcoid lesions disappear Some patients die from tuberculosis and some from right heart failure secondary to fibrosis of the pulmonary lesions others die from destruction of the bone marrow by sarcoid infiltrations

Diagnosis—Sarcoidosis has to be differentiated from perniones lupus vulgaris the deep and erythematous forms of lupus erythematosus tertiary syphilis leprosy drug granulomata and cutaneous reticuloses Reliance is placed on the morphology of the lesions the sarcoid histology, the negative Mantoux reaction the raised serum globulins and inverted albumin/globulin ratio, and X ray evidence of sarcoidosis in the bones or in the chest Radiographic findings in the lungs may suggest a diagnosis of tuberculosis pneumoconiosis or carcinomatosis The Kveim test is sometimes used This consists of the injection of an extract of proven sarcoid lymph nodes into the dermis Some 6 to 8 weeks later an indolent nodule develops which shows a typical sarcoid histology

Treatment—It is difficult to assess the value of treatment owing to the possibility of spontaneous remission A 3 months course of calciferol 150 000 units a day is worth a trial

The urine should be tested for albumin and the blood urea estimated periodically for evidence of toxicity from calciferol The skin lesions tend to improve more than the systemic ones with this treatment Isoniazid (300 to 400 mg daily) is worth a trial It has to be borne in mind that any treatment that hastens fibrosis of sarcoid lesions may in fact, shorten life by producing pulmonary fibrosis and right heart failure Intralesional injections of hydrocortisone (25 mg in 1 ml) at weekly intervals can be used to cause shrinkage and flattening of individual nodules if this is desired for cosmetic reasons or because of discomfort, as for example beneath spectacle frames

VIRUS INFECTIONS

HERPES SIMPLEX (RECURRENS) (FEBRILIS)

A malady, often recurrent consisting of outcrops of papulo vesicles which run their course in 10 to 14 days and end in scabs with minimal scarring

Clinical Picture—Without prodromal symptoms or with slight malaise the eruption begins with pink macules rapidly becoming vesicular The vesicles often show little or no erythema They may become slightly purulent or become broken and form blood scabs which detach in a few days leaving slightly depressed scars With the occurrence of further crops of lesions for the first few days of the illness all varieties of lesion—macules papules vesicles scabs and scars—can be seen in the one patient at the same time Itching is moderately severe In adults and sometimes in children there may be malaise and fever The distribution is widespread with involvement of the trunk more than the limbs also the scalp and the oral mucous membranes

Diagnosis is from papular urticaria in which the lesions appear mostly on the extensor surfaces of the limbs and consist of firm shotty itchy erythematous often golden scabbed papules sometimes much excoriated

From variola the diagnosis may be simple or extremely difficult Small pox in the unvaccinated is a malady with serious constitutional disturbance a heavy affection of the exposed parts marked sensitivity to light and all the lesions in the same stages of development but smallpox modified by vaccination and the milder variant of the malady known as alastrim may present with only one or a few lesions from which a diagnosis on clinical grounds may prove impossible Reliance must then be placed on virological and serological studies

Treatment—Varicella needs no treatment except rest in bed and calamine lotion with a normal or restricted diet depending on the presence or absence of fever

KAPOSI S VARICELLIFORM ERUPTION

This is a generalised infection with the virus of herpes simplex It occurs in infants with eczema who have been exposed to a sufferer from herpes simplex

Clinical Picture—There is a generalised eruption of varicelliform lesions high fever and general malaise

Course and Prognosis—There is a considerable mortality In those who survive the malady clears up in 2 to 3 weeks

Treatment—The best nursing is essential Secondary infection is common and possibly in part responsible for the mortality The use of antibiotics both systemically and locally is advisable The lesions should be dressed with bland applications such as calamine liniment

VACCINIA

Vaccinia is the result of deliberate or accidental inoculation with calf lymph The accidental form may follow deliberate vaccination and transference may take place on the same individual or to someone else The lesions are the same as those caused by vaccination in the susceptible and go through stages of erythema papulation vesiculation necrosis crusting and scarring The diagnosis is easy if the possibility is thought of and confirmed by enquiry

Individuals with Besnier s prurigo (atopic dermatitis) or infantile eczema are liable if accidentally or deliberately vaccinated to develop a generalised vaccinia with high fever and considerable malaise The condition has been called eczema vaccinatum and may be indistinguishable apart from the history and virological studies from Kaposi s varicelliform eruption due to the herpes virus Eczema vaccinatum may be further complicated by a severe coccal infection

Treatment—None is needed apart from protective dressings and topical antibiotics if secondary infection occurs Eczema vaccinatum needs rest in bed with good nursing and if secondary infection occurs appropriate antibiotics systemically and locally

skin, it may occur 10 to 14 days after exposure to varicella or varicella may follow at a similar interval after exposure to zoster

Histologically, there are intra epidermal mostly unilocular vesicles with swollen, grossly degenerate epidermal cells and an underlying inflammatory infiltrate proceeding to necrosis

Clinical Picture —There is a unilateral and segmental eruption consisting of grouped erythematous vesicles, with enlargement of the regional lymph nodes and a variable degree of pain in the area affected This pain may precede by a few hours the outcrop of vesicles It is severe in proportion to the patient s age being practically nonexistent in adolescents but often severe and persistent in the elderly Sometimes the pain develops its full intensity when the eruption is resolving and persists for months or years after the cutaneous manifestations have ended in scars This post herpetic neuralgia is most common in elderly patients

The lesions of zoster are at first erythematous then vesicular with erythematous margins The vesicles proceed to necrosis and dark crusts and secondary infection may then become superimposed When the scabs detach, depressed scars are left

Zoster is more serious in some sites than in others The first (ophthalmic) division of the fifth cranial nerve is often affected and the eye may then become involved with resultant opacity of the cornea and impaired vision or even with perforation of the cornea Involvement of the second division of the fifth cranial nerve causes palatal lesions in addition to those on the skin and involvement of the third division of this nerve produces lesions on the anterior two thirds of the tongue the floor of the mouth and buccal mucosa as well as on the chin When the seventh cranial nerve (geniculate ganglion) is affected there is pain and vesiculation on and behind the pinna the fauces and the posterior third of the tongue and, in addition facial palsy Involvement of the ninth cranial nerve (petrous ganglion) causes pharyngeal lesions

Course and Prognosis —Zoster once it has begun, inevitably proceeds through its various phases and ends with scarring in proportion to the intensity of the tissue reaction and amount of secondary infection in 2 or 3 weeks

Second attacks rarely if ever occur The prognosis as regards post herpetic pain is bad in direct proportion to the age of the patient

Treatment —There is no specific treatment for zoster The patient should rest in an equable temperature and a bland but not occlusive application should be applied such as calamine lotion or liniment Occlusive dressings encourage maceration and secondary infection of the lesions Suitable antibiotics locally applied are of value to control secondary infections but are no use for controlling the zoster itself For ocular involvement homatropin should be instilled and antibiotics used to control or prevent secondary infection For pain compound codeine tablets may be sufficient, or a preparation such as the following

Soluble phenobarbitone	gr ½
Tincture of gelsemium	m 10
Phenazone	gr 4
Syrup of lemon	dr ½
Peppermint water to	oz ½

½ fl oz t d s

For more severe pain, opiates may be necessary, particularly at night

VARICELLA (CHICKEN POX)

This is characterised by a polymorphic rash appearing in crops, with some constitutional disturbance and residual scarring

Ætiology —The virus is closely related if not identical to that of zoster The incubation period is 12 to 21 days

posterior pairs which bear trailing bristles The gravid female burrows in the horny layer where she deposits up to 30 eggs and then dies The larvæ hatching from the eggs have only two hind limbs until by repeated moulting they develop to mature males and females The larvæ and males burrow into hair follicles the males dying after impregnation of the females The complete life cycle takes 10 days Infection is by intimate skin contact the infestation is either a familial and household or a venereal complaint of bedfellows It may rarely spread by more casual contacts as in hand holding Itching begins about 3 weeks after infestation apparently due to the development of allergic hypersensitivity

Clinical Picture —Scabies may present as pruritus widespread eczema or in fected dermatitis urticaria impetigo or furunculosis Itching may be intolerable or inconspicuous depending on the integrity of the sensory tracts and on the mental alertness of the individual Thus in lepers imbeciles or in senile dementia there is no obvious discomfort from itching in individuals very heavily infested Secondary infection may then result in a picture re embling infective dermatitis or exfoliative dermatitis (Norwegian or crusted scabies) Nurses are very liable to become infested as a result of attending to these patients whose scales and even nails show an enormous acarine population

A history of familial incidence or of venereal exposure makes the diagnosis prob able In any widespread itchy eruption the physician should examine for scabies The sites involved and the presence of burrows should make the diagnosis clear Scabies affects thin skin areas below the collar line thus the anterior axillary folds the inner sides of the elbows the ulnar sides of the wrists and hands and the clefts of the fingers are sites commonly affected on the upper limbs On the trunk the sites most affected are the female breasts the abdomen male external genitalia and the buttocks and on the lower limbs the thighs ankles and feet in infants palms and soles are characteristically affected

The burrow is a linear slightly sinuous elevation in the skin at one end of which a darker speck marks the site of the parasite In cleanly individuals the burrows may be inconspicuous and it is best to search for them by oblique, almost tangential lighting in order to make minor elevations in the skin more obvious In less cleanly persons accumulations of dirt beside the burrows make their recognition easier Skin coloured or red follicular papules are also observed at the sites of election and elsewhere Both these types of lesion may be masked by scratching secondary infection or eczematous dermatitis In doubtful cases the diagnosis can often be made by finding adult parasites larvæ or ova This is best done by scraping open suspect burrow like lesions with a Harrison s scarifier through potassium hydroxide Microscopic examination may then reveal one or more of adult parasites, larvæ unhatched eggs or eggshell fragments

Scabies may be caught from cats and dogs but the parasites do not burrow there are only itchy papules and the disease dies out if the animal is avoided

Course and Prognosis —If untreated scabies infestations go on indefinitely *This is only likely to occur in individuals of low intelligence in whom itching may be* slight or absent By concurrent treatment of all members of the household scabies can be eliminated quickly, but if any one member of the household remains un treated or is treated at some other time recurrences are likely

Diagnosis is from pediculosis and from other causes of widespread itching eruptions associated with urticaria eczema dermatitis furunculosis and impetigo The manual lesions by themselves may suggest a contact dermatitis and a more general examination should be made in all such cases if there is the least cause for suspicion The diagnosis of scabies is made from a consideration of the history and the distribu tion and nature of the lesions and from microscopic examination Involvement of the penis and scrotum with itchy red papules is characteristic

Pediculosis corporis mostly affects the upper trunk and shoulders with scratch

WARTS (see Tumours of the Epidermis)

MOLLUSCUM CONTAGIOSUM (see Tumours of the Epidermis)

ORF (CONTAGIOUS PUSTULAR DERMATITIS OF SHEEP)

A virus infection resulting from the handling of infected sheep's heads

Ætiology—The malady may affect all handlers of sheep's heads and carcasses—shepherds, meat porters, butchers, cooks and housewives. The histological picture resembles that of cowpox, but virological studies differentiate the two conditions

Clinical Picture—The lesion usually occurs on a finger, on the hand or on the face as an œdematous inflammatory nodule. The inflammation attains its maximum intensity after 7 to 10 days, some central necrosis occurs, and the lesion gradually shrinks, disappearing after several weeks, leaving a scar. Constitutional symptoms are slight

Diagnosis is from vaccinia and milkers' nodes

Treatment—No treatment is effective in shortening the course. Topically applied antibiotics are helpful to control secondary infection

MILKERS' NODES

These are red nodules, occurring on the hands of milkers and probably due to the cowpox virus acting on someone with partial immunity. In the absence of such immunity, more typical cowpox develops, with bullous lesions on the hands or face

LYMPHOGRANULOMA VENEREUM VEL INGUINALE

This is a venereal disease caused by a virus

Clinical Picture—After an inoculation period of 7 days, a genital papule or vesicle or urethritis develops, followed in 2 weeks by enlargement of the inguinal lymph nodes which break through the skin with multiple sinuses. Involvement of the ano rectal glands from vaginal lesions may cause rectal stricture and genital elephantiasis. The infection may start as a proctitis

Diagnosis is from syphilis, soft sore, granuloma venereum and carcinoma of the rectum. The Frei test is positive

Treatment is by chlortetracycline or chloramphenicol, gr 3 every 8 hours for 14 days

GRANULOMA VENEREUM VEL INGUINALE

An infection with Donovani granulomatosis, mostly of coloured people, venereally acquired, of the anogenital region, causing nodules or vesico pustules, with slowly spreading ulceration and vegetations with serpiginous outlines and ending in extensive scarring. The Frei test is negative. *Donovania granulomatis* is responsible. The incubation is one or a few weeks

Diagnosis is from syphilitic, tuberculous and carcinomatous ulcers

Treatment is by antimony injections, streptomycin or chloramphenicol

PARASITIC INFESTATIONS

SCABIES

Scabies is an acarine parasitic infestation of the stratum corneum caused by *Sarcoptes* (*Acarus*) *scabiei*

Ætiology—The adult female is about 0 4 mm long, just visible to the naked eye, oval in shape, with two anterior pairs of limbs which bear suckers and two

individual without investigating home conditions with the aid of a health visitor All infested individuals should be treated concurrently

The hair is combed thoroughly with a fine mesh comb to unthread the nits (ova) by force In severe infestations it makes things easier if the hair is cut short. D D T application 2 per cent (B P C) is then rubbed into the scalp and not washed out for the next 24 hours the parasites are not killed immediately and may survive for a day or two or medicated (lethane) hair oil (N F) may be used in a similar way With either preparation a second application is made after an interval of 3 days Benzyl benzoate emulsion can also be used and is said to make it easier to remove the nits Lorexane a benzene hexachloride concentrate is also effective Any coccal infection that remains is dealt with afterwards by antibiotics Heat disinfestation of the bedding and headwear should be carried out

Prophylaxis —Of great importance in the prevention of scalp infestation is daily brushing and combing of the hair and a weekly shampoo This regime is often neglected when expensive permanent waving and setting is performed hence scalp infestation to day occurs mostly in young women apart from outbreaks in uncleanly families A low intelligence is common in adults with scalp infestation

PEDICULOSIS CORPORIS

The parasite is structurally similar to *P capitis* but slightly larger (4 mm long) *P corporis* is rare in peace time except among vagrants and inhabitants of common lodging houses In war conditions it tends to become more widespread

Clinical Picture —Itching of the body and scratch marks excoriations and patchy pigmentation with areas of eczematisation and lichenification sometimes with secondary infection suggest the diagnosis Exposed parts escape and the trunk is mostly affected especially the backs of the shoulders the waist and the buttocks and the proximal parts of the limbs The parasites visit the skin to feed and to deposit eggs on coarse hairs but spend most of their existence on the underclothing and bedding a completely different mode of life from sarcoptes Eggs are also affixed to fibres of textiles If the host is pyrexial the parasites move to the outer clothing and occasionally transference takes place of louse borne typhus in this way More common is transference from one person to another under overcrowded and un hygienic conditions

Course and Prognosis —Pediculosis is important not only in itself but also as the means of spread of more serious conditions such as typhus

Diagnosis is from scabies senile or general pruritus and dermatitis herpetiformis Scabies has a different distribution pathognomonic signs in the form of burrows and sarcoptes or ova may be found on scraping Senile pruritus may present with scratch marks and excoriations but parasites are not found on inspecting the clothing The physician must remember however that the patient may have put on clean underwear for his visit to the hospital Dermatitis herpetiformis affects the shoulder and pelvic girdles chiefly also the genitalia elbows and knees The physical signs are flaccid vesicles easily ruptured excoriations and patchy pigmentation There is a characteristic histology and a brisk response to treatment with sulphapyridine

Treatment —D D T powder (N F) 10 per cent liberally dusted on the patient s skin beneath the underwear is effective in controlling the personal infestation The underclothes and bedding should be heat disinfested and the seams of more super ficial garments run over with a hot iron

PHTHIRIASIS PUBIS

Phthiriasis pubis or crab louse infestation is usually acquired venereally *Phthirus pubis* is a short wide almost triangular louse 1 5 mm long and about the same width

marks, excoriations and patchy pigmentation *P capitis* may also cause scratch marks on the shoulders Parasites are found on the seams of underclothes and eggs on coarse body hairs or attached to underclothing

Treatment —The patient and all contacts must be treated concurrently Self treatment is difficult and the treatment of patients by each other is best In extensive family infestations and in epidemics or if home amenities are inadequate treatment at special cleansing stations is preferable

The full course of treatment takes 3 days On the first day the patient takes a warm bath and lathers and scrubs the body and limbs thoroughly all over with particular attention to the sites known to be most heavily involved After the bath the skin is not dried but benzyl benzoate 25 per cent is applied all over from the neck downwards using a paint brush 2 or 3 in wide Having made certain that every square inch of skin has been covered including the genitalia, perineum and toe clefts the patient dries in front of a fire puts on the previously worn nightwear and goes to bed between the previously used sheets On the second day the patient dresses in the previously worn underwear That day, a second application of benzyl benzoate is made but without a preceding bath then the patient dries before a fire and puts on clean underwear That night clean nightwear is worn and the patient goes to bed between clean sheets On the third day the patient takes a bath and the treatment is then at an end

If there is any further itching calamine lotion is applied and on no account must further applications of benzyl benzoate be made Patients sometimes give themselves repeated applications because itching often persists for a while after the two treatments and they interpret this as meaning that the infestation persists Repeated applications of benzyl benzoate may cause dermatitis medicamentosa For infants under 2 years of age, a half strength emulsion may be used Sulphur ointment (B P) (10 per cent for adults 2½ per cent for infants) may be used instead of benzyl benzoate emulsion but it is more liable to irritate the skin Underclothing nightwear and sheets are best dealt with by laundering and ironing Sarcoptes essentially lives on and in the epidermis and does not like the louse move away from the host hence it is unnecessary to disinfest bedding, blankets and the outer clothing

PEDICULOSIS

Three forms of lice live on man *Pediculus capitis* *Pediculus corporis* (*vestimenti*) and *Pediculus* (*phthirus*) *pubis*

PEDICULOSIS CAPITIS

Clinical Picture —The parasite is about 3 mm long with an oval head having two antennæ a powerful mandible and a proboscis The narrow thorax supports three pairs of legs each of which has a hook like extremity The abdomen is much wider than the thorax The eggs (nits) are laid on hairs being affixed by a cement like substance The larvæ hatch out from the egg by means of a movable lid *P capitis* may be asymptomatic and found during the course of routine examination of the scalp or it may present as itching of the scalp neck or shoulders with scratch marks, or as impetigo or pyoderma of the scalp On examination ova are found obliquely attached to hair shafts especially in the occipito parietal region In light infestations there may be eggs on a few hairs but in heavy infestations several eggs may be seen attached to one hair shaft The discovery of adult parasites on clinical examination is difficult except in heavy infestations Secondary infection causes matting of the hair an offensive odour pyoderma cervical lymphadenitis and sometimes œdema of the orbital tissues causing closure of the eyes

Treatment —Infestation may affect the family It is of no use treating the

themata may occur with or without fever they do not spread over the body surface in the same order as the exanthemata and some areas may escape In scarlatiniform toxic erythema the pattern may be coarse and the peeling more marked than in scarlatina but mouth lesions may be absent Milian s ninth day erythema is a scarlatiniform rash thought to be due to activation of a latent infection by a drug for example arsphenamine or sulphonamides The phenomenon is known as biotropism

Treatment is by finding and removing the cause Septic foci may need attention Often a cause cannot be found

FIXED ERYTHEMA

A localised and circumscribed recurrent erythema erupting in the same situation every time one particular drug is taken (see Drug Eruptions)

URTICARIA

A transient redness and swelling of the skin causing characteristic weals in the dermis or large hypodermal swellings

Ætiology —Urticaria is caused by dilatation of the capillaries and small arterioles and transudation therefrom Capillary dilatation may arise from the release of histamine or H substance and arteriolar dilatation from acetylcholine Urticaria may arise from external or internal causes The external causes include nettle stings (from their histamine and acetylcholine content) insect or jellyfish bites contact with woolly bear caterpillars or infestation with scabies In certain individuals friction causes wealing within a few seconds (dermographism or factitious urticaria) In such persons too scabies may present as urticaria In others heat is responsible and these persons also urticate from exertion or excitement (cholinergic urticaria) Urticaria from cold or from light (the yellow band of the spectrum) are both very rare Among internal causes are certain foods and drugs foci of infection intestinal parasites and hydatid cysts cutaneous reticuloses and emotional causes particularly resentment and masochism Urticaria may be dermal and present with itchy papules or with weals or it may be hypodermal and present with large non itchy swellings (giant urticaria angioneurotic œdema Quincke s œdema)

Clinical Picture —*Urticaria is conveniently divided on clinical grounds into* two forms acute or subacute single attacks and chronic or recurrent attacks

The acute form presents as itchy pink papules and weals—elevated pink areas with blanched centres brought about by the obliteration of the dermal vessels by the pressure of exudate The lesions appear suddenly with intense itching and disappear just as rapidly with the result that when the patient attends for examination physical signs may be absent Urticaria from the nettle may have pseudopodia apparently due to lymphatic spread of the injected histamine and acetylcholine Non itchy hypodermal skin coloured or pink swellings may also appear particularly around the eyes or mouth Swellings within the mouth are rare but potentially lethal at the back of the tongue or on the larynx, where they may cause obstruction of the respiratory tract The lesions may recur at intervals for a few hours or days and then cease Constitutional symptoms are usually slight or absent but the patient may be very anxious about the significance of the rash and depressed by the severe itching which interferes with sleep An emotional disturbance may lower the threshold of reaction to some antigen Sometimes a gastro intestinal disturbance precedes the eruption or foods such as shellfish or strawberries may have been eaten In other patients a drug is responsible usually aspirin a barbiturate halogen codeine phenolphthalein or quinine although many others can give the same effect. The injection of sera for example diphtheric antitoxin, or penicillin may be followed by urticaria within 10 to 14 days in the first instance or within a few hours after subsequent injections Acute local urticaria is usually caused by nettle stings mosquito bug or flea

with three pairs of legs having hook like ends Infestation may also take place in the axillæ on coarse body hairs and rarely on the eyebrows eyelashes or beard The brownish parasite hides in follicular orifices attached to hair shafts or suspends itself from two hairs and the females deposit ova on the hairs The bites of these parasites cause tiny blue spots known as 'maculæ cærulæ'

Clinical Picture —There is itching of the pubis and the sufferer often recognises the presence of the lice Bluish macules about 0 5 cm in diameter are observed but few if any, scratch marks can be seen

Treatment —Shaving the pubis is a great help Then D D T application medicated (lethane) hair oil, or benzyl benzoate application may be applied—all preferable to mercury ointment which often causes severe dermatitis Parasites on the eyelashes should be removed with forceps

INSECT BITES AND STINGS

The flea (human or dog) bed bug and gnat may cause urticarial papules with central puncta or large blisters may develop Bee wasp and ant stings may cause more violent allergic reactions in the susceptible individual

Treatment —Antihistamine creams may be applied and antihistaminic drugs taken by mouth A bee sting should be extracted if possible and weak ammonia applied Wasp and ant stings are also best treated with ammonia Dimethyl phthalate cream makes a useful repellent against gnats

ERYTHEMATOUS CONDITIONS

Erythema is a transient redness of the skin due to vasodilatation

SIMPLE ERYTHEMA

A transient redness of the skin from physical causes such as heat, cold and friction

INTERTRIGO

A shiny pink condition of opposing skin surfaces due to erosion of the superficial cells of the epidermis by mutual friction Secondary infection with monilia and cocci is common, giving rise to intertriginous (infective) dermatitis often with fissuring

Treatment of intertrigo is by suitable clothing uplift brassieres etc to prevent friction of the opposing surfaces and maceration from retention of sweat For simple intertrigo a dusting powder such as boracic talc powder is suitable If fungous infection is superimposed magenta paint is often helpful and if coccal infection develops the appropriate antibiotic Silver nitrate solution (2 per cent) is a useful application to fissures at the depths of the folds

TOXIC ERYTHEMA

A widespread reddening of the skin believed to be due to toxic agents of virus origin in measles and rubella of streptococcal origin in scarlatina due to drugs in morbilliform and scarlatiniform drug eruptions and some examples of urticaria erythema multiforme erythema nodosum etc or due to unknown causes

Diagnosis depends on a careful history and examination on the presence of fever coryza photophobia and Koplik s spots in measles occipital lymphadenopathy in rubella fever tachycardia headache vomiting circumoral pallor exfoliation of the tongue and sore throat in scarlatina drug eruptions and idiopathic toxic ery

themata may occur with or without fever they do not spread over the body surface in the same order as the exanthemata and some areas may escape In scarlatiniform toxic erythema the pattern may be coarse and the peeling more marked than in scarlatina but mouth lesions may be absent Milian s ninth day erythema is a scarlatiniform rash thought to be due to activation of a latent infection by a drug for example arsphenamine or sulphonamides The phenomenon is known as biotropism

Treatment is by finding and removing the cause Septic foci may need attention Often a cause cannot be found

FIXED ERYTHEMA

A localised and circumscribed recurrent erythema erupting in the same situation every time one particular drug is taken (see Drug Eruptions)

URTICARIA

A transient redness and swelling of the skin causing characteristic weals in the dermis or large hypodermal swellings

Ætiology —Urticaria is caused by dilatation of the capillaries and small arterioles and transudation therefrom Capillary dilatation may arise from the release of histamine or H substance and arteriolar dilatation from acetylcholine Urticaria may arise from external or internal causes The external causes include nettle stings (from their histamine and acetylcholine content) insect or jellyfish bites contact with woolly bear caterpillars or infestation with scabies In certain individuals friction causes wealing within a few seconds (dermographism or factitious urticaria) In such persons too scabies may present as urticaria In others heat is responsible and these persons also urticate from exertion or excitement (cholinergic urticaria) Urticaria from cold or from light (the yellow band of the spectrum) are both very rare Among internal causes are certain foods and drugs foci of infection intestinal parasites and hydatid cysts cutaneous reticuloses and emotional causes particularly resentment and masochism Urticaria may be dermal and present with itchy papules or with weals or it may be hypodermal and present with large non itchy swellings (giant urticaria angioneurotic œdema Quincke s œdema)

Clinical Picture —Urticaria is conveniently divided on clinical grounds into two forms acute or subacute single attacks and chronic or recurrent attacks

The acute form presents as itchy pink papules and weals—elevated pink areas with blanched centres brought about by the obliteration of the dermal vessels by the pressure of exudate The lesions appear suddenly with intense itching and disappear just as rapidly with the result that when the patient attends for examination physical signs may be absent Urticaria from the nettle may have pseudopodia apparently due to lymphatic spread of the injected histamine and acetylcholine Non itchy hypodermal skin coloured or pink swellings may also appear particularly around the eyes or mouth Swellings within the mouth are rare but potentially lethal at the back of the tongue or on the larynx where they may cause obstruction of the respiratory tract The lesions may recur at intervals for a few hours or days and then cease Constitutional symptoms are usually slight or absent but the patient may be very anxious about the significance of the rash and depressed by the severe itching which interferes with sleep An emotional disturbance may lower the threshold of reaction to some antigen Sometimes a gastro intestinal disturbance precedes the eruption or foods such as shellfish or strawberries may have been eaten In other patients a drug is responsible usually aspirin a barbiturate halogen codeine phenolphthalein or quinine although many others can give the same effect The injection of sera for example diphtheric antitoxin or penicillin may be followed by urticaria within 10 to 14 days in the first instance or within a few hours after subsequent injections Acute local urticaria is usually caused by nettle stings mosquito bug or flea

bites, it may also occur around sites of injections Dermographism, too tends to be localised to sites where clothes rub or press

Chronic or recurrent urticaria presents as itchy papules and weals and subcutaneous swellings which usually occur more in the evening but sometimes in the morning Foods and drugs are seldom found to be responsible for this type of urticaria, and the most careful search for foci of infection or of infestation is often unrewarded with success Resentment fear or ungratified libido may precipitate the condition or cause exacerbation and fatigue is often the immediate precipitant

Diagnosis—The recognition of urticaria is usually easy even if there are no physical signs at the time of the examination the history of transient swellings perhaps with itching can only mean urticaria Dermatitis herpetiformis presents with vesicles excoriations crusts and pigmentation The lesions of erythema multiforme are more persistent than those of urticaria but less itchy

Giant urticaria is differentiated from erysipelas and contact eczematous dermatitis by the absence of fever and a dusky, brawny swelling which are found in erysipelas and by the absence of vesiculation and peeling which occur in eczematous dermatitis Discovery of the cause is another matter This is often simple in the acute form but in chronic cases it necessitates the most careful history and examination directed towards the discovery of allergens toxic foci infestations physical causes or faulty attitudes of mind Further, the urticarioid lesions of the reticuloses must be borne in mind and a white cell count is always advisable in the chronic form of the malady

Treatment consists of removal or avoidance of the cause and symptomatic relief by means of antihistaminic drugs while looking for the cause The patient should be instructed to stop taking any drugs that are not essential Suspected foods should be avoided and foci of infection treated Of the antihistaminic drugs promethazine hydrochloride 25 mg in the evening or twice a day, is perhaps most useful owing to its powerful soporific effect but sometimes this action is not desired and then mepyramine maleate 100 mg up to three times a day may be more suitable The dose of any antihistaminic drug should be adjusted so as to give the best control with a minimum of unwanted side effect the dose is reduced and the drug finally withdrawn as the symptoms are relieved This particularly applies to urticaria from injected drugs such as penicillin An aperient is sometimes useful In severe forms rest in bed is advisable

In the psychogenic variety, barbiturates or bromides may be as useful as antihistaminic drugs but if the urticaria is believed to have an allergenic basis it is wise to avoid all drugs except the antihistamines Relief of the psychogenic type depends on helping the patient to understand the significance of the symptom in relation to his attitude of mind Dextro amphetamine is a valuable sympathomimetic drug for these patients in a dose of 5 mg each morning Local treatment consists of calamine lotion, to which 1 per cent of phenol or 12½ per cent of weak lead subacetate solution may be added

LICHEN URTICATUS (PAPULAR URTICARIA)

This is a form of urticaria which occurs in children

Ætiology and Pathology—The malady tends to occur more in the summer months and may recur for several years The cause is unknown but something in the home environment is important it has repeatedly been shown that removal of the patient to hospital without any other alteration in treatment may bring about a prompt remission Insect bites are responsible in a proportion of cases but in many patients a tense emotional environment seems to be another important factor

Histologically there is acanthosis spongiosis and œdema with a chronic infiltrate around the vessels of the dermis

Clinical Picture—Itchy pink or skin coloured shotty papules appear in crops mostly on the extensor surfaces of the limbs but also on the buttocks and trunk The papules soon acquire vesicular tops which may become crusted and excoriated

Course and Prognosis—The malady may persist for several weeks

Diagnosis is from scabies varicella and insect bites Scabies affects the flexor surfaces and the elementary lesions are burrows and follicular papules Penile scrotal and mammary lesions are characteristic The history may reveal other cases in the family Varicella presents with a polymorphic eruption of macules papules, vesicles and crusts The scalp is often affected and the trunk more than the limbs There are often vesicles on the buccal mucosa Insect bites may show puncta or there may be large bullæ on the legs but papular urticaria may sometimes be a generalised reaction of hypersensitivity to insect bites and puncta will not then be seen

Treatment—Any drugs being taken should be withheld and careful enquiry should be made into the child s diet with particular reference to fruits and sweets Any imbalance or excess should be adjusted An examination at the home may reveal bug infestation or flea infested animals Antihistaminic drugs in syrup form are useful for example elixir Benadryl 1 to 2 dr or elixir Phenergan in a similar dosage Removal of the child into hospital may succeed after all else has failed

URTICARIA PIGMENTOSA (XANTHELASMOIDEA)

A pigmented macular eruption with urtication

Ætiology and Pathology—The cause is unknown

Histologically there are numerous mast cells in the upper dermis in the infantile form but few or none in the adult form

Clinical Picture—In the first year of life brown macules urticarial papules and small weals are seen The lesions appear anywhere on the skin in crops each lesion starting as a papule or weal and proceeding to pigmentation The pigmented macules urticate on friction Weber has described a form in which there are telangi ectatic red macules with very slight pigmentation

Course and Prognosis—In the infantile form the lesions may disappear after several years In the adult form they are said to be more persistent and the telangi ectatic form may end fatally as a mast cell reticulosis

Diagnosis from papular urticaria in infancy is by the marked pigmentation and the presence of mast cells in the dermis The adult form may be mistaken for secondary syphilis but is recognisable by the urtication

Treatment is symptomatic by calamine lotion and a trial of antihistaminic drugs

ERYTHEMA MULTIFORME

An eruption with a marked tendency to recurrence of well defined reddened areas of skin which mostly appear on the extremities

Ætiology and Pathology—Erythema multiforme is a reaction of hypersensitivity to a variety of known or suspected causes in particular bacterial and virus infections and drug intoxications It is characteristically recurrent and is sometimes preceded by herpes simplex It is a rare complication of the X ray treatment of Hodgkin s disease

Histologically there is dilatation of the dermal blood vessels with a cellular mainly lymphocytic infiltrate around them and some serous exudation There may be some spongiosis

Clinical Picture—Erythema multiforme usually affects young adults There is no obvious seasonal incidence but a marked tendency to recurrence The distal parts of the limbs and the face are most affected and often the vermilion and mucous surfaces of the lips and the mucosæ of the mouth and genitalia are also involved

bites, it may also occur around sites of injections Dermographism too tends to be *localised to sites where clothes rub or press*

Chronic or recurrent urticaria presents as itchy papules and weals and subcutaneous swellings which usually occur more in the evening but sometimes in the morning Foods and drugs are seldom found to be responsible for this type of urticaria and the most careful search for foci of infection or of infestation is often unrewarded with success Resentment fear or ungratified libido may precipitate the condition, or cause exacerbation and fatigue is often the immediate precipitant

Diagnosis—The recognition of urticaria is usually easy even if there are no physical signs at the time of the examination the history of transient swellings, perhaps with itching, can only mean urticaria Dermatitis herpetiformis presents with vesicles excoriations crusts and pigmentation The lesions of erythema multiforme are more persistent than those of urticaria but less itchy

Giant urticaria is differentiated from erysipelas and contact eczematous dermatitis by the absence of fever and a dusky, brawny swelling which are found in erysipelas, and by *the absence of vesiculation and peeling which occur in eczematous dermatitis* Discovery of the cause is another matter This is often simple in the acute form but in chronic cases it necessitates the most careful history and examination directed *towards the discovery of allergens* toxic foci infestations physical causes or faulty attitudes of mind Further, the urticarioid lesions of the reticuloses must be borne in mind and a white cell count is always advisable in the chronic form of the malady

Treatment consists of removal or avoidance of the cause and symptomatic relief by means of antihistaminic drugs while looking for the cause The patient should be instructed to stop taking any drugs that are not essential Suspected foods should be avoided and foci of infection treated Of the antihistaminic drugs promethazine hydrochloride 25 mg in the evening or twice a day is perhaps most useful owing to its powerful soporific effect but sometimes this action is not desired and then mepyramine maleate 100 mg up to three times a day may be more suitable The dose of any antihistaminic drug should be adjusted so as to give the best control with a minimum of unwanted side effect the dose is reduced and the drug finally withdrawn as the symptoms are relieved This particularly applies to urticaria from injected drugs such as penicillin An aperient is sometimes useful In severe forms rest in bed is advisable

In the psychogenic variety barbiturates or bromides may be as useful as antihistaminic drugs but if the urticaria is believed to have an allergenic basis it is wise to avoid all drugs except the antihistamines Relief of the psychogenic type depends on helping the patient to understand the significance of the symptom in relation to his attitude of mind Dextro amphetamine is a valuable sympathomimetic drug for these patients, in a dose of 5 mg each morning Local treatment consists of calamine lotion to which 1 per cent of phenol or 12½ per cent of weak lead subacetate solution may be added

LICHEN URTICATUS (PAPULAR URTICARIA)

This is a form of urticaria which occurs in children

Ætiology and Pathology—The malady tends to occur more in the summer months and may recur for several years The cause is unknown but something in the home environment is important it has repeatedly been shown that removal of the patient to hospital without any other alteration in treatment may bring about a *prompt remission* Insect bites are responsible in a proportion of cases but in many patients a tense emotional environment seems to be another important factor

Histologically there is acanthosis spongiosis and œdema with a chronic infiltrate around the vessels of the dermis

and erythema figuratum perstans (Wende) are generally regarded as closely related if not identical

In this malady there are large annular and polycyclic pinkish grey lesions with slightly scaly borders usually with a free edge centripetally The lesions may slowly extend in one direction and fade out in another

Treatment —In some cases Fowler s solution has been reported to bring about *a remission Apart from this only symptomatic measures can be employed*

PURPURA

Purpura or the extravasation of blood in the skin may be due to many causes one of three pathological abnormalities is usually responsible There may be a defect in the vessel walls due to bacterial or chemical toxins or malnutrition there may be a deficiency of platelets or some defect in the complex process of clotting or there may be an increase of capillary pressure

In the first group is purpura in meningococcal septicæmia or in subacute bacterial endocarditis also the purpura of fulminating exanthemata—scarlet fever measles smallpox typhus etc Certain drugs for example iodides barbiturates sulphonamides may cause purpura The purpura of scurvy is due to a deficiency of the ground substance between the endothelial cells Schoenlein Henoch s purpura or allergic purpura is thought to be brought about by damage to the endothelial cells by circulating antigens

In thrombocytopenic purpura the absence of thrombocytic plugs to fill any gaps in mildly traumatised cutaneous vessels is responsible for the purpura

Purpura may also arise on the legs from hypostasis and in widespread eczematous conditions it is not unusual to see a purpuric component to the lesions on the lower extremities while those on the upper extremities show eczematous features only

Diagnosis —Purpura is differentiated from erythematous lesions by the persistence of the dark red colour on diascopy—examination through a glass spatula slide or watch glass with which pressure is applied so as to expel blood from the vessels

Discovery of the cause of the purpura depends on a full and careful clinical investigation with particular attention to the diet drugs fever enlargement of the spleen and manifestations of non cutaneous allergy or purpura such as joint swellings hæmaturia intestinal colic etc A full blood and platelet count is essential and an estimation of the clotting and bleeding times In the rare cryoglobulinæmic purpura the plasma undergoes gelification at room temperatures It chiefly affects exposed parts

Treatment is of the cause (This subject is dealt with more fully elsewhere)

THE TOXIC CAPILLAROSES

In addition to frank purpura the skin may be affected by pigmentary and telangiectatic conditions which have been given various clinical descriptions but which all show a similar histological picture suggesting some damage to the endothelium of the vessels

Ætiology and Pathology —In all types the cause is unknown

The histological picture is one of dilatation of superficial capillaries with intimal proliferation and degeneration and a perivascular infiltrate Extravasated blood cells may be seen and depositions of hæmosiderin There may be some epidermal atrophy

Clinical Picture —This varies according to the type of capillarosis

In Majocchi s disease (purpura annularis telangiectodes) the patients are usually young women and the eruption consists of discs or rings of telangiectasia with brown discolouration due to slight extravasations of blood The lesions form on the thighs or legs and very slowly extend peripherally and heal centrally with a slight residuum of atrophy

Lesions on the trunk are relatively rare An attack may be ushered in by malaise for 48 hours before the characteristic outbreak

The lesions are polymorphic and maculo erythematous papulo vesicular bullous and hæmorrhagic varieties occur They persist in one situation throughout an attack and do not show the evanescent properties of urticaria The central part of the lesions may be paler or darker than the periphery, the former indicates early bulla formation the latter is due to hæmorrhage or to brown pigmentation In either case the picture of erythema iris results

When the exudate in these cutaneous lesions has been absorbed they take on a dry, superficial fissured and scaly brownish red discoloration followed by peeling and resolution The mucosal orogenital lesions differ from those of the skin in that erosion occurs more easily with the result that a moist ulcerative pseudomembranous condition results along the vermilion surface of the lips in the mouth or on the glans penis or mucosa of the vulva There may also be pain and swelling of joints fever and albuminuria but usually subjective symptoms including itching are slight.

The Stevens Johnson syndrome is a severe variant of erythema multiforme with exudative bullous and erosive cutaneous lesions extensive and distressing involvement of the mouth and lesions on the conjunctiva and cornea of the eye which may go on to pannus and blindness This malady is accompanied by fever and malaise

Course and Prognosis —Attacks of erythema multiforme usually clear spontaneously after 2 or 3 weeks but recurrences after intervals of months or years are common The common form leaves no sequelæ but the severe form may lead to dimness of vision or blindness

Diagnosis is from other bullous conditions on the hands and elsewhere and from other erythematous conditions Thus pompholyx dermatitis herpetiformis pemphigus and pemphigoid lupus erythematosus and urticaria may all at one time or another have to be excluded Pompholyx may present with large bullae but there is no marked erythematous component unless secondary infection occurs Dermatitis herpetiformis presents with intensely itchy vesicular and eroded lesions on the shoulders buttocks elbows, knees or elsewhere but there is little or no erythematous halo to the lesions In pemphigus the bullæ are flaccid and extend when lateral pressure is applied to them (Nikolsky s sign) They may arise from normal coloured skin In pemphigoid the bullæ are tense but Nikolsky s sign is positive There may be pink areas around the bullæ This malady may in fact so closely conform to the clinical and histological pattern of erythema multiforme as to be regarded as senile erythema multiforme perstans Subacute and cutaneously disseminated lupus erythematosus may resemble erythema multiforme but the distribution is more on the face and upper part of the chest In doubtful cases a raised erythrocyte sedimentation rate leucopenia and increased serum globulins will support the diagnosis of lupus erythematosus Urticaria is characterised by the short lived and recurrent nature of its lesions which come and go first at one site then at another

Treatment is supportive by rest (in bed in severe forms) and bland local applications such as calamine lotion or Lassar s paste Internally antihistaminic drugs such as mepyramine maleate or promethazine hydrochloride may prove helpful In the severe Stevens Johnson form active measures must be taken to avert the serious eye conditions that can result The administration of corticotrophin is an urgent measure to help the patient through the severest phase A dose of 50 mg every 6 hours is advisable for 4 days after which the drug is gradually withdrawn

ERYTHEMA ANNULARE CENTRIFUGUM (DARIER)

This is believed to be a variant of erythema multiforme though some examples have seemed to be more akin to dermatitis herpetiformis The conditions called erythema simplex gyratum (Jadassohn) erythema chronicum migrans (Lipschutz)

on perniotic legs of young women Ulceration is common with considerable scarring and disfigurement In some cases the differential diagnosis may prove impossible except after a period of observation

In erythema induratum (Whitfield) (*q v*) the patients are *usually women* between 30 and 45 years of age This malady sometimes called nodular vasculitis is probably a variant of erythema nodosum but the lesions which come out in crops are more persistent than those of erythema nodosum and leave discoloured hard areas in the skin Ulceration is uncommon In periarteritis nodosa the lesions are more persistent and necrotic and they may appear anywhere on the body or limbs

Treatment —The patient should be kept in bed until the nodules have subsided Chemotherapeutic and antibiotic drugs are best withheld because their administration may be followed by an exacerbation of the skin condition Symptomatic treatment is best with the minimum use of drugs of all kinds excepting aspirin which may be given with benefit Vitamin supplements an adequate diet and subsequently a period of convalescence and return to good housing conditions are desirable A bland local application for example calamine lotion or titanium dioxide paste is *suitable*

If the Mantoux reaction is undergoing or has recently undergone conversion it is important that the patient should not come into contact with tuberculous individuals except inadvertently and unavoidably for some months at least If the patient is a nurse she should not be allowed even after convalescence to take up nursing of tuberculous patients Every patient with erythema nodosum should be investigated by clinical and radiographic means for evidence of tuberculosis elsewhere

ERYTHEMA INDURATUM

This is of three types erythema induratum of Bazin a subcutaneous tuberculide the subcutaneous sarcoid of Darier Roussy and erythema induratum of Whitfield (nodular vasculitis)

BAZIN S DISEASE

This affects the unshapely calves of young women with perniosis It is believed to be a tuberculide localised to the calves because of the defective circulation (see p 1244)

DARIÉR-ROUSSY SUBCUTANEOUS SARCOID

This is similar to Bazin s disease in appearance but does not ulcerate The Mantoux reaction is negative there is a sarcoid histology and the condition reacts sluggishly if at all to antituberculous drugs (see p 1246)

ERYTHEMA INDURATUM OF WHITFIELD (NODULAR VASCULITIS)

This presents as recurring tender hard subcutaneous nodules in the legs of women of 30 to 45 years of age The condition is not a tuberculide but is a variant of erythema nodosum possibly of streptococcal origin There is no specific treatment, elastic supports often give relief

LUPUS ERYTHEMATOSUS

An erythematous and atrophic malady presenting in two forms the first circumscribed benign cutaneous and chronic the second malign systemic and acute An intermediate form occurs—chronic or subacute disseminated lupus erythematosus

CHRONIC DISCOID LUPUS ERYTHEMATOSUS

Ætiology and Pathology —The cause is unknown

The characteristic features of the histology include in the chronic discoid variety

In Schamberg's disease (progressive pigmentary dermatosis) men are usually affected on the legs more often than elsewhere but sometimes at sites of pressure Dark reddish brown puncta the 'cayenne pepper' spots are visible in a zone of brownish skin The lesions may itch and they slowly enlarge but may ultimately resolve spontaneously, leaving some pigmentation A similar condition is sometimes seen on the legs of patients with varicosities

The pigmented lichenoid purpuric dermatitis of Gougerot and Blum presents with discrete and agglomerated papules, with petechiæ pigmentation and telangi ectasia The lesions may appear on the trunk or on the limbs

Angioma serpiginosum (Hutchinson) presents with telangiectasia which by clear ance at one site and spread at another comes to acquire an annular or a serpiginous arrangement The body or limbs may be affected

Treatment—As no cause is at present known for these conditions, none other than supportive treatment can be offered The patient should be investigated for foci of infection, diabetes and vascular hypertension

OTHER FORMS OF CAPILLAROSIS

Occasionally extensive eruptions of capillarosis are seen on the lower extremities buttocks, trunk, shoulders, elbows and elsewhere of young men It has been shown in some cases that textiles are responsible but the exact cause whether it be dye mordant or something else, has not yet been determined The eruption usually persists for several months No treatment is effective in bringing about earlier remission

ERYTHEMA NODOSUM

This is an outbreak of tender nodules on the legs and sometimes on the forearms which in their healing stage have the appearance of bruises (erythema contusiforme)

Ætiology and Pathology—The cause is a reaction of hypersensitivity in the subcutaneous vessels of the limbs which bring about an inflammatory reaction in and around the vessel walls (nodular vasculitis) The sensitising causes include tubercle bacilli, streptococci and occasionally meningococcal and other infections In the United States a common cause is coccidioidomycosis The lesions may also develop when chemotherapeutic and antibiotic drugs release organismal products to which the patient is sensitised

Histologically there is a focal dense infiltrate of neutrophil leucocytes and lympho cytes in the more superficial hypoderm The infiltrate invades the vessel walls (venules) and there is endothelial proliferation and thrombosis

Clinical Picture—Often after a sore throat or an upper respiratory infection the patient usually a child or young adult complains of tender swellings on the fronts of the legs and perhaps on the forearms The lesions are at first red and later brownish blue or even greenish, obtuse nodes with somewhat ill defined limits There may be a dozen or more lesions on the two limbs The natural course of the lesions is to undergo slow resolution disappearing in a few weeks without visible permanent change The nodules do not break down (except a rare form occurring with severe exacerbations of ulcerative colitis)

Course and Prognosis—Erythema nodosum clears spontaneously after a few weeks The lesions in themselves are of no import but they are of great significance in that they may indicate the presence of a primary tuberculous infection with hyper sensitivity Other manifestations of tuberculosis may follow and every patient with erythema nodosum should be kept under periodic observation for some months In cases due to hypersensitivity to streptococci the prognosis is better The erythrocyte sedimentation rate is a useful guide in following the progress of erythema nodosum

Diagnosis is from erythema induratum (Bazin) erythema induratum (Whitfield) and periarteritis nodosa In the first named the lesions are larger and usually arise

Treatment —When the clinical diagnosis of lupus erythematosus has been made it is wise to have the erythrocyte sedimentation rate estimated because if this is within normal limits it is most probable that the condition is in fact the benign cutaneous form of the malady but if the erythrocyte sedimentation rate is increased and particularly if there is also leucopenia the condition is probably systematised and potentially malign no matter how benign the cutaneous manifestations may seem to be An estimation of the serum protein may then reveal an increase of globulins and an albumin/globulin ratio of less than unity

The treatment of discoid lupus erythematosus is in the present state of knowledge empirical and the clinician can only treat every case on its merits giving whatever remedy in his experience produces the best results

Mepacrine 0 1 g up to three times a day is successful in many cases in bringing about a remission It should be taken until the lesions fade or until the skin becomes yellow whichever is the sooner and then the dose is gradually reduced a course lasting anything up to 3 months Periodic urinary examinations are a sensible pre caution and the patient should be examined at regular intervals so that the drug can be withdrawn at once should a toxic eruption begin to show itself Alternative oral remedies include mercury with potassium iodide and quinine Sulphonamides are contraindicated Vitamin supplements may be indicated and crude liver injec tions sometimes bring about relief Isoniazid has not been found of value in lupus erythematosus

Another valuable treatment in some cases is weekly injections of bismuth oxy chloride 0 2 g in 1 ml intramuscularly into the upper quadrant of the buttock the course extending up to 8 or 12 injections Injections of gold (sodium aurothiomalate) have been advocated but the risks of gold dermatitis are too considerable to justify the use of this remedy except for some very good reason If used the dosage should be low (10 to 25 mg) the urine should be tested and the body surface inspected before each injection and the course should comprise a total dosage of not more than 250 mg in about 12 weeks The drug is cumulative

Local treatment is also of great importance and value Local applications have no healing action but they can protect the lesions from mechanical injury screen them from light and provide cosmetic camouflage Titanium dioxide paste can fulfil all these functions or the patient may prefer the more æsthetic make up preparations of the cosmetic firms As an ultra violet screening cream salol 10 per cent or para aminobenzoic acid 15 per cent can be incorporated in a vanishing cream base but must be reapplied frequently if sweating is heavy

Local therapeutic practices include applications of carbon dioxide snow (—78 C) or slush the former being compressed into a pencil and applied for about 10 seconds to thickened red areas and the latter made by adding acetone to carbon dioxide snow and then applying it for one or two brief freezes by means of a camel hair brush or cotton wool on a probe The aim is to bring about an inflammatory reaction which will be followed by the formation of smooth and supple scarring Snow has a deeper action than slush and is more suitable for localised thickened lesions

Contraindicated in lupus erythematosus are sulphonamides by mouth and ultra violet irradiation X rays or radium locally the former because an exacerbation may result the latter because exacerbation or even malignant changes (epithelioma) may be initiated by these means

SYSTEMATISED LUPUS ERYTHEMATOSUS

Ætiology —The cause is unknown Over 90 per cent. of cases occur in women usually between the ages of 20 and 40 The disease may arise in a patient with chronic discoid lupus erythematosus or it may follow exposure to sunlight or the exhibition of drugs such as sulphonamides iodides thiourea and organic arsenicals

hyperkeratosis with keratotic follicular plugging, atrophy of the prickle cell layers liquefactive degeneration of the basal cell layer and basophilic degeneration of the collagen and elastic tissue, with a lymphocytic infiltrate mainly distributed around the vessels and cutaneous appendages

Clinical Picture —This form affects the face particularly across the nose and malar ridges (bat s wing lupus), also on the forehead, chin lower lip and ears Young and middle aged women are more often affected than men, and the condition is not seen in children The lesions are well defined, red rings, ovals or irregular shapes with marked thickening peripherally and paler atrophic centres On the surf ce are white or grey closely adherent scales, and horny plugs may be visible in the ostia of the follicles The patches remain stationary or slowly extend at one site while atrophic scarring develops at another Other sites characteristically affected include the vertex of the scalp (scarring baldness with redness and follicular plugging) the mucosæ of the cheeks (leucoplakia and reddened areas with erosions), the hands (red, scaly thickened patches on the backs of the fingers between the joints chilblain like redness around the nail folds, lupus pernio of Hutchinson) and the arms and upper part of the trunk In chronic or subacute disseminated lupus erythematosus many of these sites may be affected in the one patient

Course and Prognosis —In patients in whom the diagnosis of chronic discoid lupus erythematosus is firmly established by pathological as well as clinical means the course is usually of intermittent clearance and relapses on the skin with on the whole a gradual extension Sometimes the disease becomes inactive and scarring alone remains Transition from the chronic discoid to the acute systematised form rarely occurs but there are examples of the systematised form which present with lesions apparently so benign and chronic that the incorrect diagnosis of the chronic discoid form is made unless examination of the blood is carried out

Diagnosis is from lupus vulgaris and other granulomatous processes from carcinoma cutaneous reticulosis rosacea and light sensitisation dermatitis

Lupus vulgaris usually begins in childhood lupus erythematosus in adult life Lupus vulgaris shows translucent yellowish nodules which may be scattered around the edge of the scarred area, lupus erythematosus is characteristically a centrifugal process with adherent scaling and central atrophic scarring Lupus vulgaris may destroy the cartilage of nose or ears and cause great disfigurement Lupus erythematosus does not affect cartilage but is confined to the skin

Syphilitic gummata characteristically break out on the surface following the destruction of cartilage and bone, but they may also present as infiltrated irregular, soft reddish brown nodulations Psoriasis of the face may resemble lupus erythematosus but the scales are white, mica like and easily detached and typical psoriatic lesions are present elsewhere Seborrhœic dermatitis causes greasy scaling on a reddened background but the lesions itch and are more numerous and less well defined than in lupus erythematosus Sarcoidosis nodules more closely resemble lupus vulgaris but may mimic lupus erythematosis profundus In these circumstances biopsy is essential Lymphomata (Spiegler-Fendt sarcoids) are dome shaped dusky nodules with little or no epidermal change

Lupus erythematosus on the alæ nasi may resemble carcinoma cutis The redness may be slight, the border markedly raised the centre ulcerated, but follicular plugging is present and there is no pearly edge If the diagnosis cannot be established on clinical grounds alone biopsy will decide it One form of lupus erythematosus resembles rosacea in distribution but the lesions are persistent and associated with some degree of atrophy and there is no vasolability Light sensitisation dermatitis may resemble the less infiltrated form of lupus erythematosus but the lesions are more diffuse eczematised and itchy Chilblains on the fingers resemble lupus erythematosus but they only occur with cold weather, whereas lupus erythematosus persists throughout the year

ised lupus erythematosis must be considered in all cases of inexplicable pyrexia or when there is wasting anæmia, albuminuria purpura or lymphadenopathy also in the presence of acute neurological episodes The diagnosis is confirmed by the presence of a raised blood sedimentation rate leucopenia hyperglobulinæmia album inuria and the discovery of the L E cell

Treatment—Corticotrophin or cortisone may bring about a remission and pre vent relapse The effect on the ultimate prognosis is less favourable although a few apparent cures have been reported An initial dose of 50 mg of corticotrophin intra muscularly 6 or 8 hourly should be given and gradually reduced Renal involvement is a contraindication as renal failure may be precipitated presumably due to ischæmic changes following healing of the arterial lesions

The patient with chronic discoid lupus erythematosus and laboratory evidence of systematised lupus erythematosus should avoid sunlight extremes of temperature and the drugs mentioned previously

DRUG ERUPTIONS (DERMATITIS MEDICAMENTOSA)

Almost any drug may cause a skin eruption at one time or another but some drugs have this property to a much greater extent than others and certain individuals are unduly susceptible to drugs Drugs may produce ill effects from their external or from their internal use in several ways

External use Drugs applied externally may give rise to toxic effects in the following ways—(*a*) Contact eczematous dermatitis as from the topical use of sulphona mides antibiotics surface anæsthetics antiseptics antihistaminics etc (*b*) Light sensitisation as from sulphonamides tar quinine etc (*c*) Toxic effects on various organs after absorption as from sulphonamides flavine mercury (liver kidney) resorcin (thyroid) etc

Internal use Drugs taken internally may cause toxic effects by—(*a*) Toxic action on the skin immediate or accumulative (*b*) Induction of allergic hypersensitivity in the cutaneous vessels (*c*) Toxic action on bone marrow liver kidneys thermo static centre etc causing purpura skin infections nutritional deficiency hæmaturia albuminuria fever etc (*d*) Indirect toxic or allergic action through the destruction of bacteria and the release of their toxins (*e*) Destruction of organisms capable of synthesising vitamin B in the gut (*f*) Interference with absorption from the gut (*g*) Destruction of competitors of monilia in the gut (*h*) By competing for enzymes that are essential for cellular welfare (*i*) Aggravation of a pre existing dermatosis (*j*) Activation of virus infections herpes simplex zoster

Drug eruptions may also be of mixed external and internal origin A drug (for example penicillin sulphonamide) may be used topically in the first instance and cause an eruption from its subsequent internal use or it may be used internally in the first instance and cause an eruption when it is subsequently used by local application

Clinical Pictures—Many drugs cause nonspecific eruptions and a few have specific effects

The nonspecific eruptions in their simplest forms are morbilliform and scarlatini form erythemata In greater degrees of intensity there may be a resemblance to erythema multiforme with or without bulla formation or the toxic action on the bone marrow or cutaneous blood vessels may be sufficient to cause purpura Urticaria implies vascular hypersensitivity More specific effects include fixed erythemata pruritus exfoliative dermatitis pigmentation eczematoid psoriasiform acneiform lichenoid seborrhœic or pityriasis rosea like eruptions granulomata stomatitis and urethritis Usually there is something atypical about the eruption that differentiates

Pathology —The commonest findings at necropsy are chronic obliterative pleurisy pericarditis, perihepatitis and perisplenitis There are small warty endocardial vegetations in one third of the cases

Histological examination shows proliferation and fibrinoid degeneration of collagen in the supporting tissues of the serosal surfaces, myocardium, mediastinum retro peritoneal tissues and skin There is fibrinoid degeneration and necrosis of the connective tissue of the media of small arteries and arterioles, with proliferation of the endothelium, sometimes leading to thrombotic occlusion of the vessel these changes are usually found in the kidney, spleen and skin

In the kidney there may be focal necroses of capillary loops and the basement membrane of glomerular capillaries may be thickened and eosinophilous In the spleen the central artery of the Malpighian bodies may be surrounded by concentric rings of connective tissue

Clinical Picture —The manifestations of the disease are those of a febrile, wasting illness with inflammation of serous membranes depression of the bone marrow and finally, symptoms of vascular changes in viscera, especially the skin and kidney

The joints are frequently affected usually with a slowly shifting polyarthritis There may be swelling of the joints but permanent deformity is uncommon Pleurisy with effusion and pericardial effusion occur Hypertension is uncommon but albuminuria and microscopic hæmaturia are frequent The spleen and lymph glands may be enlarged anæmia is common and purpura may be found Diarrhœa is the commonest gastro intestinal symptom, and there may be vomiting abdominal pain and jaundice Mental changes are common, they vary from anxiety to toxic confusional states and delirium Involvement of the nervous system may cause epilepsy and rarely lymphocytic meningitis, encephalomyelitis or peripheral neuritis Examination of the fundus oculi may show hæmorrhages exudates and papillœdema Cutaneous manifestations may be marked slight or absent temporary or persistent On the face and chest there may be erythematous patches resembling erythema multiforme There may be red petechiæ or telangiectases on the tips of the fingers splinter hæmorrhages under the nails and a condition resembling chilblains on the fingers The palms may show ill defined erythematous blotches There may be redness and leucoplakic changes in the mouth on the lips or in the ano genital region

Laboratory findings include an increased red cell sedimentation rate leucopenia and the discovery of the L E cell on mixing the patient s plasma with her own or someone else s blood cells This cell is a polymorphonuclear leucocyte which has ingested degenerate nucleoprotein material and it is rarely seen except in systematised lupus erythematosus

Course and Prognosis —The course varies considerably The illness may be acute and fulminating from the beginning with high remittent fever prostration and joint pains, alternatively there may be acute exacerbations in a subacute or chronic form of the disease which may be precipitated by exposure to sunlight or exhibition of the drugs previously mentioned Death may occur in a few weeks The disease more usually runs a subacute course of many months or a chronic course of 5 or even 10 years Relapses and remissions are common the remissions rarely lasting longer than a year Death is usual within 5 years Spontaneous cure of the disease has been described but must be very rare Patients are often seen with chronic discoid lupus erythematosus who have a raised blood sedimentation rate leucopenia and hyperglobulinæmia who nevertheless continue in a reasonable state of well being the number of these patients who develop the florid manifestations of systematised lupus erythematosus is unknown but the long term prognosis is unfavourable

Diagnosis —The facial lesions may resemble erysipelas erythema multiforme or dermatomyositis When the joint manifestations are prominent the disease will have to be differentiated from acute rheumatism and rheumatoid arthritis Systemat

Psoriasiform arsenic gold mepacrine
Purpura antihistamines arsenic aspirin barbiturates carbromal chloral hydrate halogens mercury penicillin phenazone phenytoin Pyramidon quinidine quinine salicylates Sedormid sera sodium aminosalicylate sulphonal sulphonamides
Stomatitis antibiotics arsenic barbiturates bismuth gold halogens mercury phenacetin phenazone phenobarbitone phenolphthalein quinine, salicylates sulphonamides
Tuberculides (exacerbation) calciferol
Urticaria most of the drugs in this list arsenic aspirin barbiturates bromides cocaine derivatives iodides penicillin phenacetin phenolphthalein quinine sera and sulphonamides are common causes
Vesiculation (varioliform) halogens sulphonamides
Zoster arsenic

Course and Prognosis—Many eruptions are transient clearing rapidly after withdrawal of the drug but penicillin urticaria may persist for several weeks and halogen eruptions may continue to worsen after the drug has been withdrawn Some injected drugs for example gold are cumulative in their effects and dermatoses caused by them often worsen steadily after the last injection Inorganic arsenic has delayed effects the first signs appearing some years after the drug is first taken possibly even several years after its use has been abandoned

The prognosis depends on the possibilities of bringing about elimination of the drug and on the presence or absence of toxic effects on the liver kidneys and bone marrow

Diagnosis—The possibility of drug causation or aggravation has to be borne in mind in many dermatoses particularly if there is something atypical in the eruption and questioning has to be directed accordingly Analgesics aperients hypnotics sedatives and antibiotics are particularly suspect Withdrawal of a suspected drug may be followed by immediate improvement With nonspecific eruptions and when the patient has been taking more than one drug a test dose is justifiable This should only be given when the dermatosis has subsided and one tenth of the previous therapeutic dosage should be given in the first instance because if the full dose is given an unnecessarily violent reaction may result

Prevention and Treatment—The history may indicate sensitivity to one or more drugs Some drug eruptions result from neglecting to enquire into this possibility Potent drugs are sometimes used without sufficient justification In every case it is a useful self discipline to ask oneself Do the advantages likely to be obtained by giving this drug outweigh its possible ill effects? Whenever there is a choice a drug of lesser toxicity and sensitising potential should be used Especial care is necessary when there is albuminuria

To make treatment easier it is as well to tell the patient of possible side effects of a drug This encourages discontinuation of the drug immediately untoward symptoms develop and prevents further toxicity For most drug eruptions withdrawal of the drug is all the treatment that is necessary or in fact possible An aperient or an enema is sometimes useful when there is reason to think that some of the drug remains in the bowel Specific treatments are indicated in a few conditions For halogen eruptions sodium chloride or ammonium chloride may be given in a dose of 5 to 10 g daily In severe cases with toxæmia intravenous normal saline infusions should be given daily 100 ml on each occasion for a week

Heavy metal intoxications (gold bismuth mercury) are treated with dimercaprol (B A L) 2 ml 4 hourly gradually reduced to 2 ml daily in courses lasting a week with a week of intramuscular crude liver extract interposed The pigmentation of argyria is permanent The effects of inorganic arsenic (raindrop pigmentation keratoses carcinomata, hepatitis) are irreversible The keratoses are best treated with

it from the disease it mimics but this is not always so the lichenoid eruption due to mepacrine sometimes being identical to "idiopathic lichen planus possibly because it is in fact, lichen planus, triggered off by the drug Many toxic eruptions remain unexplained on a drug basis Sometimes this is due to drug contamination of foods for example the use of phenolphthalein to tint icing pink and the possibility of other food "processings" being the cause of toxic eruptions is a matter for speculation

The more common manifestations and some of the drugs that may cause them include

- Acneiform pustular bromides, corticotrophin, iodides sometimes sulphonamides
- Albuminuria bismuth, calciferol gold mercury, sulphonamides sera.
- Alopecia (cicatricial) gold mepacrine
- Bullous (pemphigoid) barbiturates, chloral, cinchophen, dapsone, halogens phenazone, phenolphthalein, phenytoin, quinine, salicylates streptomycin sulphonamides
- Coryza arsenic, iodides salicylates sulphonamides
- Cyanosis phenacetin sulphonamides
- Eczematoid antihistamines, arsenic, gold halogens, mepacrine, mercury, penicillin quinine sulphonamides
- Erythemata, morbilliform and scarlatiniform most of the drugs mentioned elsewhere in this list also atropine, belladonna, digitalis ephedrine, insulin, ipecacuanha, phenylbutazone procaine, rhubarb santonin turpentine
- Erythema multiforme like acetanilide, barbiturates, bismuth, dapsone, gold quinine sera sulphonamides thiouracil
- Erythema, fixed (localised and recurrent) phenolphthalein most commonly, also reported from arsenic, amidopyrine barbiturates, bismuth bromides cinchophen gold iodides mercury penicillin phenazone, phenytoin quinine salicylates sulphonamides
- Erythema nodosum iodides salicylates sulphonamides, thiouracil
- Exfoliative dermatitis arsenic (organic), barbiturates bismuth, gold, mepacrine, mercury phenolphthalein phenytoin streptomycin sulphonamides
- Fever arsenic barbiturates sulphonamides
- Genital lesions phenazone phenolphthalein, quinine
- Gingivitis bismuth mercury phenytoin (hypertrophy)
- Granulomatous, vegetating, ulcerative halogens
- Herpes simplex arsenic
- Infective (seborrhoeic) dermatitis arsenic gold, mepacrine mercury penicillin sulphonamides
- Keratoses carcinomata arsenic (inorganic)
- Leucopenia amidopyrine arsenic barbiturates phenazone sodium amino salicylate sulphonamides
- Lichenoid arsenic, bismuth, gold mepacrine
- Light sensitisation arsenic, gold mercury quinine sulphonamides
- Lupus erythematosus sulphonamides
- Papulo necrotic tuberculides calciferol
- Pigmentation arsenic barbiturates bismuth, corticotrophin gold mepacrine, phenazone phenolphthalein, quinine silver
- Pityriasis rosea like antihistamines arsenic, gold mepacrine
- Pruritus general codeine morphine opium also arsenic bismuth gold mepacrine penicillin phenobarbitone phenolphthalein Pyramidon, sulphonamides
- Pruritus anogenital chloramphenicol chlortetracycline codeine phenolphthalein

the flexural areas In the toxic forms the exfoliation develops uniformly during or after a course of treatment with one of the drugs mentioned In both these forms fissuring or secondary infection may develop and there may be considerable enlargement of the regional lymph nodes

In the idiopathic lymphadenopathic erythroderma the skin is dark brown and shiny and the exfoliative element less marked There is marked enlargement of the lymph nodes and those at the axillæ and groins may be observed bulging the skin In the male the breasts may become swollen and tender The patient may have other possibly toxic manifestations including psychosis cardiac irregularities etc There may be a moderate intermittent fever

In lymphoblastomatosis with erythroderma the skin is bright red and coarsely peeling The lymph nodes may be moderately enlarged and the liver and spleen palpably enlarged

In all forms of erythroderma heat loss is excessive and care must be taken not to expose the patient unduly during examination on the other hand occlusive ointments may interfere with heat loss and cause pyrexia There may be considerable loss of hair and thickening of the nails

Course and Prognosis —This depends on the cause The form due to over-treatment of a dermatosis slowly resolves with suitable bland treatment The toxic forms persist for some weeks or months depending on the rapidity of elimination of the toxic substance The severest examples may have a fatal outcome from broncho pneumonia hepatitis or nephritis The idiopathic form tends to clear after some months but may recur even after several years The lymphoblastic form is steadily progressive to a fatal ending

Diagnosis —The recognition of erythroderma is a simple matter and the diagnosis of the different forms has been indicated above But there are two conditions that can closely resemble erythroderma The first is psoriasis universale which can develop without any over treatment The history should help and the skin is bright red with mica like scales The nails may be abnormal in either condition but more particularly in psoriasis The blood count is normal in psoriasis but also in the earlier stages of lymphoblastic erythroderma The histology of both conditions is distinctive

The second condition which may be mistaken for erythroderma is pemphigus foliaceus (erythematodes) Here the pathological process of poor cell cohesion is so superficial (in the granular layer) that any bullæ that form are quickly broken and a picture of exfoliation and infection results Nikolsky s sign is positive and the histology characteristic the granular layer being exposed to the surface

In infants extensive staphylococcal pemphigus may have erythrodermatous characteristics (Ritter s disease)

Treatment —In all forms only bland applications should be used and they should not be occlusive Oily calamine lotion zinc cream or hydrous ointment are all useful Care should be taken that the patient does not get chilled by exposure

In the over treatment form this soothing treatment combined with such sedation as may be necessary is all that is required the patient being kept at rest in equable surroundings and the skin cleaned with a bland vegetable oil

In the toxic form dimercaprol is valuable where arsenic gold mercury or bismuth is believed to be responsible It is best given in a course of 6 days 2 ml 4 hourly on the first day 2 ml twice daily on the second third and fourth and 2 ml daily on the fifth and sixth days After this course daily intramuscular injections of 4 ml of crude liver extract may be given with advantage for a week followed by a second course of dimercaprol The patient should also receive vitamin supplements

In toxic erythroderma due to non metallic poisons the courses of dimercaprol are omitted but the intramuscular injections of crude liver extract may be given with benefit 4 ml daily

In the idiopathic form corticotrophin is invaluable for bringing about a remission

carbon dioxide snow applications and the carcinomata by X irradiation or carbon dioxide snow, depending on their size and situation. *Toxic effects from organic arsenic* need treatment with dimercaprol.

Rest in bed is advisable in the more severe eruptions. Plenty of fluids should be given. The urine should always be examined and treatment adjusted accordingly. *A blood count* is also advisable to detect hæmoglobin deficiency (as with dapsone) or leucopenia (as with sulphonamides, etc.). In purpuric eruptions the thrombocyte count should be estimated. If it is normal vitamin C should be given in large doses. If there is evidence of severe marrow depression, blood transfusions may tide the patient over the worst phase. In all forms of drug eruption multiple vitamin supplements are a rational treatment and crude liver injections are often helpful. Antihistamines are invaluable for controlling urticaria from penicillin, and once the optimum dosage has been found they are best given in gradually smaller doses until they can be abandoned. Local treatment is often unnecessary or may consist of the application of a lead and calamine lotion.

ERYTHRODERMA (EXFOLIATIVE DERMATITIS)

Erythroderma is a persistent redness of the skin, with exfoliation (as opposed to erythema, which is transitory).

Ætiology and Pathology.—There are numerous causes for this type of reaction. It may develop as a result of the over-treatment of eczema, dermatitis, infective dermatitis or psoriasis. It may be a toxic phenomenon following the administration of organic arsenicals, mercurials, sulphonamides, gold, barbiturates, bismuth or mepacrine. It also occurs in an idiopathic form as lymphadenopathic erythroderma, a condition which is probably toxic and sometimes recurrent, with much pigmentation (lipomelanic reticulosis).

Another form of erythroderma is associated with lymphoblastomatosis (*l'homme rouge*), sometimes preceding or following the clinical phenomenon of mycosis fungoides and ultimately being accompanied by an increase of circulating lymphocytes. An erythrodermatous form of sarcoidosis also occurs.

Histologically there is hyperkeratosis and parakeratosis, spongiosis with a variable degree of acanthosis and œdema, and an infiltrate of lymphocytes and histiocytes in the upper dermis and around the vessels and epidermal appendages. In the idiopathic form, there is much pigment in the melanophores of the dermis and the lymph nodes show little disorganisation but much melanin, hæmosiderin and lipoid material in the reticulum cells. In the lymphoblastomatous form there may be microabscesses in the prickle cell layer and either a basal infiltrate indistinguishable from the benign type already described or a massive infiltrate of lymphocytes or of lymphoblasts with eosinophils, neutrophils, histiocytes and reticulum cells, with many mitoses. This infiltrate is dense in the upper dermis and patchy in the deeper parts. The histological pattern of the lymph nodes is disorganised. It is sometimes difficult or impossible to differentiate, except by repeated sections at 3 to 6 months interval, between the relatively benign lipomelanic form and the malign reticulosis, but the clinical features are usually fairly distinctive, the former being characterised by much pigmentation and slight or moderate peeling, the latter by redness and marked peeling. The histology of the lymph nodes, the peripheral blood and bone marrow may all help to establish the diagnosis. Erythrodermatous sarcoidosis shows the histological features of sarcoidosis.

Clinical Picture.—In the over-treatment forms there is a history of a preceding more localised dermatosis and of its extension to the condition observed following the application of one or more known irritants or sensitisers. There is coarse peeling with moderate redness and sometimes a greasy texture to the scales, particularly in

Diagnosis—Guttate psoriasis has to be differentiated from a secondary papulo squamous syphilide on the basis of absence of lymph node enlargement or of mucosal involvement The skin lesions are not infiltrated or ham coloured in psoriasis and although the scalp may be affected there is no loss of hair

Infective (seborrhœic) dermatitis presents with dirty grey scales of greasy texture beginning as follicular papules which affect by preference the face sweat grooves and flexures the scalp is involved with loss of hair

In pityriasis rosea the lesions are pink or fawn coloured with a centripetal free border to the collarette and the malady usually affects the trunk and proximal parts of the limbs

Lichen planus presents with itchy violaceous polygonal papules with a waxy glance mostly on the flexor surfaces

Treatment—Calamine liniment makes the best local application All measures directed towards improving the general well being are likely to help including a holiday vitamin supplements and (if under skilled observation) ultra violet irradiation with a suberythema exposure daily

(2) Localized Extensor Psoriasis is another way in which the malady begins and it may persist with fluctuations for the remainder of the patient s life without any obvious disturbance in the general health This type may begin in childhood or in adult life and is most common at and just below the tip of the elbows and over the patella and patellar tendon Other sites often affected include the lumbo sacral region the calves the forearms and the scalp or any of these areas may be affected alone The lesions may be nummular discoid circinate polycyclic or irregular in shape (psoriasis geographica) There is usually no itching

Diagnosis—Nummular eczema may resemble a nummular psoriasis but the lesions are papulo vesicular exuding or crusted A single chronic patch of psoriasis has to be differentiated from lichen simplex lupus vulgaris tuberculoid leprosy tertiary syphilis Bowen s disease and superficial basal cell epithelioma (*q v*)

Treatment—The patient is best advised that treatment is only necessary for the sake of appearance and that the condition in no way interferes with general health and is not contagious At the same time a pessimistic view that psoriasis is incurable and nothing can be done about it is not only unjustified but positively harmful It is true that the fundamental cause of psoriasis is unknown and therefore cannot be removed nevertheless the precipitating factors causing recurrences and exacerbations are often discernible and it may be possible to adjust or remove them and so give relief to the skin condition The importance of day by day traumata in this form must be remembered particularly with regard to prognosis

In the localised form benefit is often derived from daily applications of a solution of coal tar to the lesions with a camel hair brush combined with soft paraffin ointment to any cracked or excessively dry areas as required Solution of coal tar may also be applied in a 6 to 12 per cent concentration with or without salicylic acid 2 to 4 per cent in ointment of wool alcohols simple ointment or soft paraffin ointment Ointment of wool alcohols mixes most with skin fats and so brings the tar into more intimate contact with the skin Simple ointment and to a greater extent soft paraffin ointment mitigate the action of the tar and they are often more useful because of their soft paraffin content

(3) Flexural Psoriasis is most commonly seen in the obese and friction between opposing surfaces of skin plays an important part The axillæ submammary folds umbilicus genito crural folds and intergluteal cleft may be affected Secondary infection may occur particularly with monilia Sometimes diabetes coexists Psoriasis of the genito crural region may be either the result or the cause of pruritus vulvæ The lesions are sharply marginated smooth shiny red areas

50 mg 8 hourly being given and the dose gradually reduced as improvement results The condition may remain clear after withdrawal of the drug or it may recur in which circumstances it is best to give cortisone in the smallest dose which gives relief and to withdraw it gradually as soon as possible

In the lymphoblastomatous form corticotrophin may give symptomatic relief without objective improvement beyond a slight diminution of scaling Radioactive phosphorus is worth a trial Otherwise treatment is symptomatic and supportive

SQUAMOUS DERMATOSES

PSORIASIS

Psoriasis is a common condition of sharply marginated, reddened areas of skin with abnormal scaling The malady is most variable in its intensity and course, remissions recurrences and exacerbations being a characteristic feature

Ætiology and Pathology —The fundamental cause is an unknown biochemical fault in epidermal cell formation resulting in abnormal horn cells The fault is inherited and psoriasis occurs in 1 in 5 on the average of children of a psoriatic parent The first signs are usually noted in the second or third decades but it may first appear in children under 10 or in persons over 30 or even in old age Histologically, there is parakeratosis (nucleated cells in the stratum corneum) some hyper keratosis and irregular acanthosis (hyperplasia of the stratum mucosum) with such gross variability in the thickness of the epidermis that at one site there may be only a few cells between the dermis and the surface while nearby there may be a large number There is clubbing of the interpapillary rete ridges of the epidermis In the dermis there is vascular dilatation particularly in the upper part and a patchy lymphocytic infiltrate around the vessels and the cutaneous appendages

Precipitating factors are the hereditary predisposition, infections unfavourable physical and emotional environments, emotional conflict and trauma to the skin

Clinical Picture —From the clinical standpoint, psoriasis is best divided into six types

(1) Guttate, post infective psoriasis of children
(2) Localised extensor psoriasis
(3) Flexural psoriasis
(4) Widespread psoriasis
(5) Pustular psoriasis of the palms and soles
(6) Psoriasis of the nails

(1) Guttate Psoriasis in Children may have no obvious precipitant but often there is a history of an infection particularly streptococcal throat infections some 3 weeks before the onset of the rash It may begin after scarlet fever or varicella measles or mumps suggesting that the malady is a type reaction of certain individuals to various infections

The lesions are raindrop sized pink, flat topped papules with scaling which is at first inconspicuous *Itching is slight or absent The scaling is made more obvious by scraping (grattage) a papule with a spatula (not a finger nail !)* This makes visible the silvery mica like delicate scales and pin point bleeding indicates the presence of dermal papillæ very near the surface The lesions are widespread even generalised in distribution but the face and hands tend to be less affected

Course and Prognosis —Provided the condition is not over-treated this form of psoriasis often gradually clears in about 3 months In others it may persist with enlargement of some of the lesions to coin like (nummular) or discoid areas *At any time in life there may be recurrences or recrudescences* of psoriasis usually of the discoid type the guttate form rarely returning

It is important in widespread psoriasis to do nothing that may cause an extension of the malady and possibly lead to its generalisation or to exfoliative dermatitis For this reason alone its more rigorous treatment needs daily supervision by a trained observer Dithranol has a justifiable reputation for relieving psoriasis but this treatment is best reserved for in patients Dithranol ointment (B P) (0 1 per cent) is in any case too weak to be of value while strong dithranol ointment (1 per cent) is too strong for out patient use and for the first trial of this substance Its injudicious use can cause aggravation or even exfoliative dermatitis It is best to start with 0 5 per cent *in soft paraffin and to raise this to 1 per cent 1 5 per cent or 2 per cent* in stages as may be required Dithranol causes an inflammatory reaction and stains the skin a violet brown colour Its daily application is continued until the lesions look paler than the surrounding skin It is then withheld and soft paraffin ointment is substituted Dithranol causes a severe conjunctivitis if it gets into the eyes

In resistant psoriasis T.A B injections are sometimes successful in intravenous doses of 25 50 and 100 million organisms at 5 to 7 day intervals the aim being on each occasion to attain a temperature peak of 103 F

Sedation with bromides promethazine hydrochloride or barbiturates may be necessary and depressed patients may do well on amphetamine sulphate 5 mg each morning Dietetic and vitamin treatment is ineffective except in so far as conditions of obesity on the one hand or malnutrition on the other may require adjustment X ray irradiation (100 r three times at weekly intervals) is very effective in clearing individual patches but is only justifiable for special purposes such as the clearance of a resistant patch on a site for operation

Psoriasis does not respond to corticotrophin or cortisone

Emotional factors may be dealt with according to their relative importance by reassurance open discussion and moral support by drug abreaction or even by psychoanalysis Suggestion and hypnosis are undoubtedly helpful while they are used but are likely to cause an excessive rebound when the moral prop is withdrawn

Complete clearance of all lesions is the aim but the physician may well decide to be satisfied with some 80 to 90 per cent of clearance particularly if the psoriasis has appeared early in life and has been aggravated by relatively trivial stimuli At this stage the patient should be encouraged to live with the psoriasis and not to be forever trying to clear off the last traces by any new method recommended by all and sundry It must be stressed that the treatment of psoriasis is the treatment of each individual according to the physical or psychical defects that are discovered it is not a routine matter of one regime or another

A holiday in congenial surroundings with relaxation and isolation from the telephone may be as effective as any of the above measures

(5) Psoriasis of the Palms and Soles —This condition is probably identical with pustular bacteride and one form of acrodermatitis pustulosa continua

Clinical Picture —In pustular psoriasis the lesions are golden yellow from the beginning and do not go through a vesicular stage The pustules occur on palms or soles less often on fingers or toes amongst areas of red skin with dyskeratotic scaling Psoriasis may also occur on the palms as patchy dyskeratotic areas with some adjoining erythema On grattage silvery scaling is apparent Either form may occur with or without psoriatic lesions elsewhere

Course and Prognosis —Pustular psoriasis is extremely chronic and often fails to respond to remedies that are effective elsewhere including X rays Its relief depends on the discovery and treatment of any infective focus (particularly streptococcal) the avoidance of local physical traumata and treatment of any metabolic or emotional factors that seem to be relevant

Diagnosis is from pompholyx in which the vesicles are skin coloured and become yellow at a later stage

Diagnosis —The presence of psoriasis elsewhere usually helps in differentiation from infective dermatitis and from intertrigo

Treatment depends on the cause Obesity, diabetes various causes of pruritus vulvæ (*q v*) need attention Locally, magenta paint can be used to control any infective element After this, a dusting powder may be helpful or simple ointment with a 2 per cent solution of coal tar A 2 per cent salicylic acid and sulphur ointment may prove useful

(4) WIDESPREAD PSORIASIS may develop *de novo* or it may follow guttate psoriasis or localised psoriasis of the extensor or flexor surfaces The reason for the extension may be some infection over treatment, intoxication, bad environmental conditions or emotional stress due either to environmental or to personal difficulties There may be no constitutional disturbance but mental depression is common A persistent widespread rash may easily induce the leper complex and this accounts for the depression in some cases but in others the variation of mood is parallel with changes in the state of the skin neither preceding nor following them and suggests that fluctuations in intensity of the psoriasis and mood changes are often due to a common cause The involvement may be widespread, subtotal or universal The lesions may be nummular, discoid figurate polycyclic or annular The Koebner phenomenon may be present in which scratching the skin causes the development of psoriasis in the line of scratch The skin in the centre of annular lesions does not show this reaction having become refractory for a time to this stimulus The sites commonly affected include the scalp (where the scales may be in several diminishing layers giving a limpet like appearance—rupioid psoriasis), the trunk, particularly the lumbo sacral region the extensor surfaces of the limbs and the nails Sometimes the flexures are also affected The face and hands usually escape except in severe examples of the disease Arthritis of the rheumatoid type is commonly associated with extensive psoriasis

Course and Prognosis —This severe form of psoriasis is of prolonged duration and uncertain often unfavourable prognosis unless the causal factors can be controlled

Treatment —It is advisable to admit patients with extensive psoriasis to hospital for investigation and treatment The investigations are directed to infective metabolic and emotional disorders and specific treatment is given accordingly Nonspecific treatment for the psoriasis is best carried out by the Goeckerman régime or some modification of it In this the patient s skin is cleaned of ointment with liquid paraffin each morning then general ultra violet irradiation is given a first degree exposure with treatment of plaques of psoriasis with a second degree exposure if this is practicable The patient next takes a warm bath (to which may be added 2 to 4 oz of solution of coal tar to 25 gallons of water if itching is severe) In the bath the whole surface may be cleaned with a toilet soap but forcible removal of scales with a coarse brush is inadvisable After drying from the bath the patient is treated by the inunction of 6 per cent solution of coal tar in soft paraffin, excepting the flexural lesions which are better dealt with more gently with Lassar s paste alone or with 2 per cent of the solution of coal tar The scalp needs special attention Equal parts of Teepol and water with 1 per cent of glycerin make an effective shampoo, followed by the inunction of up to 12½ per cent of solution of coal tar in the ointment of wool alcohols or in emulsifying ointment To this may be added 2 per cent of salicylic acid and 2 5 per cent of ammoniated mercury (Soft paraffin is too sticky and messy in areas of coarse hair and Lassar s paste causes matting and is very difficult to remove) Oil of cade 12½ per cent may be used instead of the solution of coal tar or 2 per cent each of salicylic acid and of sublimated sulphur may be preferred in emulsifying ointment The régime may include autohæmotherapy 10 ml on four occasions every 5 days

the herald patch distribution of the eruption cleavage line tendency and centripetal scaling are characteristic Lichen planus is usually very itchy the lesions give a waxy glance , show pseudoscaling have a characteristic distribution and often involve the oral mucosa and the external genitalia

Course and Prognosis—If untreated the condition may persist indefinitely but it seems to have no effect on the general health

Treatment—The malady sometimes responds well to general ultra violet irradiation or to calciferol by mouth in a dose of up to 150 000 units a day for up to 3 months with fortnightly urine examinations and estimations of the blood urea to detect early signs of intoxication from the drug

Locally salicylic acid ointment is suitable

PARAPSORIASIS DISCOIDES (parapsoriasis en plaque xanthoerythroderma perstans) presents as yellowish red discs and ovals non itchy occurring on the trunk and limbs usually in adults aged 30 or more without constitutional disturbance

Histopathology is not distinctive There is focal parakeratosis and spongiosis and nonspecific infiltrate in the dermis a picture resembling a low grade dermatitis

Clinical Picture—Non itchy brown pink plaques appear on the trunk and the limbs with slight scaling and with no constitutional disturbance There may be slight atrophy

Course and Prognosis are both uncertain Parapsoriasis en plaque may persist for months or years and a proportion of the cases pass on to poikiloderma (telangiectasia atrophy pigmentation and depigmentation) or to reticulosis in one of its many guises (exfoliative dermatitis mycosis fungoides etc) The prognosis must be non committal and periodic physical examinations and if necessary biopsies should be made for early evidence of a reticulosis

Treatment is most unsatisfactory the malady resisting all efforts of the physician including ultra violet irradiation calciferol and various nonspecific remedies

PARAPSORIASIS LICHENOIDES (parakeratosis variegata) presents with reddish brown scaly flat topped papules in reticular pattern chiefly on the extensor surfaces of the limbs the neck and the trunk The condition is slowly progressive but benign

Diagnosis is from secondary syphilis and lichen planus (*q v*)

Treatment is symptomatic and supportive

PITYRIASIS LICHENOIDES ET VARIOLIFORMIS ACUTA is a fourth and uncommon form of parapsoriasis of more sudden exanthematous onset with lichenoid and varioliform lesions yellowish brown and crusting It resolves spontaneously after weeks or months leaving depressed scars The palms soles and mucosæ escape but the lymph nodes may be enlarged

Diagnosis is from varicella secondary syphilis drug eruptions pityriasis rosea and lichen planus (*q v*)

Treatment is symptomatic and supportive

PITYRIASIS ROSEA

PITYRIASIS ROSEA is a scaly disease of limited duration characterised by the appearance of a herald patch a few days before a generalised eruption

Ætiology and Pathology—The cause is unknown It often follows an upper respiratory infection or slight fever and may be a virde Second attacks are rare

The histopathology is not distinctive There is some parakeratosis and a non specific cellular infiltrate in the dermis

Clinical Picture—Children and young adults are mostly affected There is often a history of malaise coryza and of sore throat a week or two before the onset

Treatment —Locally, soft paraffin ointment with 2 per cent. salicylic acid is a useful application Tonsillectomy has been followed by relief in some cases X rays in fractional (100 r) exposures up to four may help, but as often fail

(6) Psoriasis of the Nails usually occurs with psoriasis elsewhere but occasionally it is the only evidence of the disease

Clinical Picture —The mildest form is a thimble like pitting of the nail plates This may vary in extent from a single pit on one nail to confluent affection of several nails and is very characteristic of psoriasis rarely being seen in other diseases affecting the nails

In the next degree of severity psoriasis causes brown or yellow discolouration affecting the sides or the distal parts or the whole surface of the nail plates In this form the nails are usually not thickened but when psoriasis affects the nail beds and matrices, the nail plates become thickened opaque, dull and friable Paronychial involvement causes deformity with longitudinal or transverse ridging and grooving

Diagnosis —Psoriasis unguium has to be differentiated from tinea unguium and eczema dermatitis affecting the nail folds Rarer possibilities include syphilis lichen planus and idiopathic nail dystrophies

Ringworm usually affects one or a few nails of the hands and feet in asymmetrical fashion and is often associated with ringworm elsewhere in toe clefts on the feet or hands or in the groins Microscopic examination of nail shavings removed with the edge of a glass microscope slide reveals fragments of mycelium The nails in ringworm are usually a dirty grey colour partly destroyed and deformed with longitudinal or transverse ridging and a powdery friable surface

Syphilis or lichen planus are recognised by evidence of the presence of these maladies elsewhere Idiopathic nail dystrophy is a discoloured and deformed condition of the nails without evidence of psoriasis or of other skin disease elsewhere

Treatment —In the minor forms treatment is not necessary unless the patient demands it The results of treatment are always uncertain but weekly applications of thorium-X 1500 e s u per ml for about 3 months often seem to give good results This treatment is preferable to the use of X-rays or medication with liquor arsenicalis Salicylic acid ointment makes a satisfactory local application Trauma to the nail folds and excessive drying or degreasing must be avoided

PARAPSORIASIS

Parapsoriasis is a descriptive term for various forms of persistently abnormal scaling of the skin They are rare and of unknown cause but are probably distinct conditions

Parapsoriasis Guttata (pityriasis lichenoides chronica) occurs as guttate grey brown scaly lesions the scales often being concave and not having the mica like appearance and pinhead bleeding points of psoriasis They are distributed on the trunk and limbs The lesions itch little if at all and there is very little redness of the skin around the abnormal scaling The lesions persist, with slight fluctuations for an indefinite period and there is no constitutional disturbance It usually affects young or middle aged adults

Pathology —There is parakeratosis and hyperkeratosis slight atrophy of the stratum mucosum and a nonspecific infiltrate of slight degree around the vessels and appendages in the dermis

Diagnosis is from secondary syphilis lichen planus drug eruptions and pityriasis rosea After a time the prolonged course rules out syphilis and pityriasis rosea In syphilis mucosal changes condylomata enlarged lymph nodes and evidence of a primary lesion may be found and the lesions are ham coloured In pityriasis rosea

brittle The plaques are pink or red scaly areas having a resemblance to psoriasis on the one hand and lichen simplex on the other, but they differ from both these conditions in that central circles or polycyclic areas of normal skin are present Ectropion may occur The mucous membranes are not affected There is no obvious constitutional disturbance

Course and Prognosis —The malady comes on insidiously and continues indefinitely in spite of treatment A spontaneous remission may occur after several months

Treatment —There is no evidence that the administration of vitamin A shortens the duration Œstrogens may seem to bring about a remission but their evaluation is difficult Treatment is symptomatic with applications of salicylic acid ointment or a mixture of this with an equal part of glycerin of starch

DYSKERATOSIS FOLLICULARIS

Dyskeratosis follicularis or Darier s disease is a rare condition due to an inherited abnormality of horn formation

Ætiology and Pathology —The cause is unknown but an abnormality of vitamin A metabolism is suspected

The highly characteristic histology consists of hyperkeratosis and papillomatosis with keratotic plugging and dyskeratotic corps ronds and grains in the upper epidermis with lacunæ at the epidermo dermal junction which results in the formation of vegetations

Clinical Picture —Early in life the child is noted to have dirty grey keratotic plugs on the skin The flexures and the hair bearing areas are affected most Secondary infection may lead to moist warty nodulation and an offensive odour The finger tips show pinhead and smaller depressions on the epidermal ridges They are peculiar to this malady

Course and Prognosis —The course is prolonged but the malady does not disturb the general health except from the effects of secondary infection Some degree of mental retardation is not uncommon

Diagnosis is from acanthosis nigricans in which there are velvety pigmented folds and wartiness and from pemphigus vegetans and dermatitis vegetans (*q v*)

Treatment is symptomatic Ten per cent salicylic acid ointment is a useful application Vitamin A is ineffective

LICHENOID DERMATOSES

These eruptions are of widely differing ætiology and pathology but they have in common some degree of similarity in their physical signs

LICHEN SIMPLEX CHRONICUS

This is a common condition in which oval areas of pinkish brown thickened skin develop at sites of repeated friction (see Sensory Disorders)

LICHEN PLANUS

This is a disorder of uncertain duration in which itchy flat topped shiny violaceous papules appear on various parts of the body

Ætiology and Pathology —The cause is unknown It is suspected to be of virus origin and set off by varied noxæ including drugs physical agents nutritional deficiencies and emotional stresses

Histologically the picture is characteristic but it is modified by the amount of

The *first change* in the skin is the herald patch, somewhere on the trunk at the axilla or on a thigh, occasionally *more distally on a limb*. The lesion is an oval, rosy plaque becoming fawn coloured with scaling, the free edges of the scales being centripetal. Itching is *slight or absent as a rule*. The herald patch may be missed. The generalised eruption begins *a week or two later* and is usually confined to the trunk and proximal parts of the limbs. It often extends up the neck and down the arms and *forearms*, but the face, lower thighs and legs are seldom affected.

Two types of *generalised* eruption are seen: the more usual macular and plaque form and the follicular *papular form*, in which, however, a few plaques are always present as well. The plaques start as pink macules which extend to become oval '*medallions*' which, on the trunk, lie parallel to the ribs; they vary in size from *0.5 cm. to 2 cm. or more*. Scaling is not apparent at first but, after a week or 10 days, the lesions become fawn coloured and scaling begins from their centres causing a *centripetal* arrangement of the free border of the scaling. In the early stage when *this feature* is not apparent, it can be demonstrated by scraping a lesion so as to detach the looser scales. There are no mucosal changes and the lymph nodes are not enlarged.

The follicular papular variety is more difficult to recognise, but the manner of *onset and* the distribution should give rise to suspicion and the discovery of medallions makes the diagnosis clear.

Course and Prognosis.—The total course is usually about 6 weeks but it may *last only* 4 weeks or continue for anything up to 10 weeks. Pityriasis rosea is modified in xerodermatous and seborrhœic subjects. Its course is prolonged if, owing to a misdiagnosis, treatment is given with fungicides. In these circumstances, it may become papular vesicular, eczematised and distressingly itchy.

Diagnosis is from secondary syphilis, drug eruptions, tinea circinata and infective dermatitis. In secondary syphilis, the examination of the genitalia, mucous surfaces and lymph nodes reveals other evidence of that disease. Pityriasis rosea-like drug eruptions are usually in some way atypical. Tinea circinata is usually more acute with vesiculation as well as marginal peeling; the lesions are circular rather than oval; they are few in number and may appear on the face; the scalp too may be affected with scaling and short broken hairs. Microscopy reveals mycelia and *spores*. Infective dermatitis is recognised by its grey greasy scales and sweat area distribution.

Treatment.—Reassurance, explanation and calamine lotion are usually all that are required. The patient need not be isolated. Warm but not hot baths may be taken. If any doubt exists, the Wassermann reaction should be tested. Over-treatment must be avoided. To hasten peeling, general ultra-violet irradiation is sometimes given and the course may be shortened by about a week in this way, but there is rarely any justification for this procedure.

PITYRIASIS RUBRA PILARIS

This is a rare chronic skin disorder characterised by red follicular papules with horny spines, keratoderma of the palms and soles and psoriasis-like plaques of a bright pink colour.

Ætiology and Pathology.—The cause is unknown. A defect of vitamin A metabolism is suspected. It may be a follicular variant of psoriasis.

Histologically there is follicular keratosis and plugging with an infiltrate around. The psoriasis-like plaques show parakeratosis and a nonspecific infiltrate.

Clinical Picture.—There are widespread groups of pink or red follicular papules with keratotic tips on the body and limbs. The hairy backs of the proximal phalanges show follicular keratoses. There is marked thickening and dirty discolouration with fissuring of the horn on the palms and soles and the nails become deformed and

lichen nitidus lichen sclerosus et atrophicus and lichen amyloidosis (q v) The diagnosis depends on a careful consideration of the elementary lesions their waxy glance' their distribution and the presence of orogenital lesions Lichen planus may be non itchy and in the early stage of evolution the lesions may be atypical Hence it is sometimes necessary to reinspect a patient after a week s interval with a view to coming to a firm diagnosis It may also be necessary to perform biopsy a very useful procedure because of the highly characteristic histology in lichen planus

Treatment —There is no specific treatment for lichen planus and each patient must be dealt with according to the relative significance of emotional drug physical or other factors that become evident when taking the history

Sedation is usually necessary either by an evening dose of a barbiturate such as butobarbitone gr 3 or with gr ¼ doses of phenobarbitone two or three times a day in addition

The withdrawal of any drugs the patient may have been taking is advisable if they are suspected as causal for example gold or mepacrine Appropriate detoxicating remedies such as dimercaprol should be given when indicated and more specific supporting treatments such as crude liver injections and vitamin supplements are justifiable

Bed rest is a valuable prescription for subacute widespread lichen planus or when the history suggests that fatigue may be an important factor Such adjustments to the patient s mode of living that may seem necessary play an important part in treatment and unless these psycho physical factors are dealt with the malady may prove intractable

Certain drugs have a reputation for relieving resistant lichen planus They include mercury and potassium iodide mixture intramuscular injections of bismuth (0 2 g in 1 ml) or of mercury salicylic arsonate (0 06 g in 2 ml) or a short course of Fowler s solution A short course of corticotrophin may bring about a remission

Fractional X ray exposures (75 r up to four weekly treatments) to confluent patches or fortnightly applications of thorium X (1 500 e s u per ml) often help to tilt the balance in the patient s favour

Other local applications are not of great value Phenol 1 per cent in zinc cream or calamine lotion may be used as an antipruritic

LICHEN NITIDUS

This is a rare eruption of uncertain ætiology consisting of lichenoid papules in which there are focal areas of tuberculoid histology enclosed as it were between claws of epithelium The overlying epidermis is atrophic The collagen and elastin are degenerate A tuberculous cause has not been established and the condition may in fact be a variant of lichen planus

Clinical Picture —Non itchy skin coloured or pink shiny flat topped papules occur in close set groups particularly on the penis the flexor surfaces of the forearms or on the abdomen

Course and Prognosis —The lesions persist indefinitely but may finally fade away without residual pigmentation

Diagnosis is made from lichen planus by the absence of itching and pigmentation and the characteristic histology

Treatment is ineffective Success has been claimed for iodine taken by mouth in the form of Lugol s solution The patient should be examined for any possible tuberculous focus

LICHEN SCLEROSUS ET ATROPHICUS

A condition of lichenoid papules ending in atrophy and sclerosis affecting both sexes commoner after 30 years of age rare in children

atrophy or hypertrophy present and by the extent of involvement of hair follicles. Hence, terms such as lichen planus atrophicus lichen planus hypertrophicus (lichen planus verrucosus) and lichen plano pilaris (lichen planus follicularis) Lichen spinulosus et folliculitis decalvans of Graham Little is a variety of lichen plano pilaris affecting the scalp

There is hyperkeratosis, thickening of the stratum granulosum, either atrophy of the stratum mucosum or an irregular acanthosis and, depending on the intensity of the dermal infiltrate a variable degree of liquefactive degeneration of the stratum germinativum which in extreme cases may result in histological or even clinical evidence of bulla formation (lichen planus bullosus) The rete ridges may be of saw tooth' type or in atrophic areas absent in hypertrophic cases there is papillomatosis In the upper dermis, immediately subjacent to the epidermis, is a heavy infiltrate almost entirely composed of lymphocytes with a few histiocytes

In lichen plano pilaris the same histological features are observed at and around the hair follicles

Clinical Picture—Lichen planus most characteristically affects the buccal mucosæ the fronts of the wrists the lumbosacral region, the external genitalia the medial aspects of the thighs, the shins, calves and ankles it may appear on the palms or soles and anywhere on the body though rarely, if ever, on the face Scratching sometimes causes linear lesions (Koebner s phenomenon) or exposure to sunlight may localise the rash Involvement of the scalp with lichen plano pilaris may end in the picture of pseudopelade (*q v*) and rarely the nail matrices are affected and the nails dystrophic and deformed as a result

The elementary lesion of lichen planus as seen on the skin is a violaceous, polygonal flat topped shiny papule Sometimes the papules are only a shade darker than the surrounding skin Often Wickham s striæ and spots can be seen upon them—grey streaks and spots of pseudo scaling thought to be colour changes caused by the thickened stratum granulosum The individual papules often enlarge or run together to form extensive plaques

Central healing, often somewhat atrophic is common, resulting in lichen planus annulare On the penis this is most characteristic and the lesions here are often non itchy Resolution of lichen planus is nearly always accompanied by a great deal of pigmentation It is not unusual for all the lesions to clear except those on the legs which may on the contrary, become verrucose and persist indefinitely

Lichen plano pilaris presents as shiny follicular papules with a violaceous rim the papules often being grouped The process ends in atrophic scarring at first violaceous later white and in patchy baldness

Lichen planus of the mouth gives rise to white slightly raised polygonal spots and white streaks and delicate feathery patterns Ulceration or redness are unusual and the lesions are either symptomless or give rise to a sensation of slight roughness

Lichen planus of the nails is very rare Involvement of the nail matrices may cause grey rough dystrophic nails

Course and Prognosis—Lichen planus is extremely variable and unpredictable in its course, no doubt depending on the possibilities of controlling the causal factors The subacute form may in fact persist for months new lesions appearing while others become inactive and are concerted into pigmented macular remnants The chronic form may persist indefinitely or clear at some sites but not at others The legs are particularly likely to be affected by chronic and often hypertrophic lichen planus Even after complete disappearance of all lesions fresh outbreaks may occur some months or years later

The development of carcinoma on lichen planus in the mouth has been described in a very few cases lesions on the vulva because of the irritation they cause may result in leucoplakic changes and carcinoma

Diagnosis is from psoriasis parapsoriasis guttata syphilis, warts lichen simplex,

(phrynoderma) The cause is believed to be a deficiency of vitamins A and C and the malady is mostly seen in children

A somewhat similar picture may occur in the follicular variety of xeroderma (keratosis suprafollicularis)

An eruption of oval areas of lichen spinulosus on the trunk and limbs may occur with fungous infections of the feet (lichen trichophytide)

Pathology—In xeroderma the stratum granulosum is deficient In avitaminosis A and C there may be perifollicular hæmorrhages

Diagnosis is from lichen plano pilaris in which the papules have violaceous rims and on the scalp cause a variety of folliculitis decalvans

Treatment—Depending on the cause treatment consists of vitamin supple ments elimination of a fungous infection or attention to xeroderma or lichen planus Salicylic acid ointment may be applied

LICHEN SCROFULOSORUM

This is an eruption of skin coloured or pink lichenoid papules usually occurring on the trunk in childhood There is often also tuberculosis of lymph nodes bones or joints etc a strongly positive Mantoux reaction and a tuberculoid histology (see Tuberculides)

LICHEN AMYLOIDOSIS

This is a localised cutaneous form of amyloidosis presenting as itchy elevated nodular plaques on the shins resembling hypertrophic lichen planus The diagnosis is confirmed by staining for amyloid (see Amyloidosis)

LICHEN URTICATUS

This is a papular urticaria of childhood The lesions resemble varicella more than lichen (see Urticaria)

PITYRIASIS LICHENOIDES CHRONICA

PITYRIASIS LICHENOIDES ET VARIOLIFORMIS ACUTA

(See Parapsoriasis)

PARAPSORIASIS LICHENOIDES

(See Parapsoriasis)

LICHENOID ERUPTION OF AXILLÆ (FOX FORDYCE DISEASE)

This malady occurs mostly in women as pink or brown dome shaped grouped papules in the axillæ also sometimes at other apocrine sites the areolæ of the nipples the umbilicus pubic region and the perineum Itching is severe

Ætiology and Pathology—The cause is unknown

There is follicular hyperkeratosis and plugging acanthosis and a chronic inflam matory infiltrate around the apocrine glands

Treatment consists of œstrogens by mouth and salicylic acid 2 per cent in hydrous ointment locally Fractional X ray exposures 100 to 150 r weekly up to a total of 600 r may prove helpful

ACNEIFORM DERMATOSES

These are eruptions in which acuminate papules provide the most characteristic feature

Ætiology and Pathology—The ætiology is unknown

The histopathology is characteristic and includes hyperkeratosis and acneiform follicular keratotic plugging atrophy of the stratum mucosum, œdema of the upper dermis with homogenisation of the collagen and an inflammatory infiltrate in the deeper parts of the dermis, without obliterative vascular changes as seen in scleroderma

Clinical Picture—The malady presents with genital and extragenital lesions In both sexes the latter consist of roughly circular pinkish grey atrophic parchment like patches with a few comedones At flexural sites there may also be white lichenoid papules and scleroderma like plaques without comedones

In the male the genital lesions may be similar to those already described if they are on the shaft of the penis There may be a fibrous constriction of the prepuce causing phimosis On the inner surface of the prepuce, at the coronal sulcus and on the corona and glans there is a variable degree of atrophy and sclerosis Atrophy may be confined to the penile meatus and this may later cause some urethral stenosis or the whole surface of the glans may be irregularly thickened dry white and hard a condition known as balanitis xerotica obliterans In the female the atrophic and sclerotic changes may affect the labia minora or majora and the adjoining skin of the perineum and perianal region Itching is variable but may be intense The severest cases may have bullous lesions owing to interference with lymph drainage

Course and Prognosis—Lichen sclerosus et atrophicus continues indefinitely but may undergo considerable spontaneous improvement There are no serious complications on the extragenital skin but on the penis urethral stenosis may occur and on the vulva intense itching and scratching may lead to leucoplakic and carcinomatous changes

Diagnosis is from the localised form of scleroderma (morphœa) macular atrophy, leucoplakia and atrophic vaginitis with kraurosis

Morphœa presents as an oval firm white or pink, shiny plaque with a lilac halo Atrophy is not marked except sometimes in the later stages There are no comedones The histology is different from that of lichen sclerosus et atrophicus In macular atrophy there are soft bulgings giving a hernia like feeling on pressure Leucoplakia only affects mucous surfaces Lichen sclerosus et atrophicus of the vulva may be complicated by leucoplakia Atrophic vaginitis presents as shrinkage of the vaginal orifice (kraurosis vulvæ) with patchy pigmentation depigmentation atrophy and telangiectasia of the mucosa of the vulva The labia minora are often atrophic or absent

Treatment—There is no specific treatment It has been claimed that vitamin E by mouth is of value The ointment of wool alcohols or hydrous ointment make useful local applications Meatal stenosis may need suitable attention If leucoplakia or carcinoma supervene on the vulva excision is called for, but excision of the perineal and perianal skin is unnecessary because carcinoma does not develop on extragenital lesions of lichen sclerosus

LICHEN STRIATUS

This is a rare malady occurring usually in children A band of lichenoid papules erupts usually in the long axis of a limb and after a few weeks or months involutes spontaneously Itching is slight or absent

The histology is that of chronic dermatitis

Diagnosis is from lichen planus linearis

Treatment is symptomatic and supportive

LICHEN SPINULOSUS (KERATOSIS FOLLICULARIS)

This is a condition of widespread or grouped horny follicular papules The widespread form involves in particular the extensor surfaces of the limbs and trunk

Diagnosis is from sycosis acneiform tuberculides syphilides drug eruptions and rosacea

In sycosis involvement is of coarse hair bearing areas whereas acne involves areas of glabrous skin and the borderline between coarse hair bearing areas and glabrous skin The two conditions may coexist

Acne agminata presents as grouped translucent papules particularly on the eye lids nose and penis

Acneiform syphilides are papulo pustular but without comedones, but syphilis may also aggravate a pre existing acne vulgaris

Halogens too particularly iodides may cause acneiform eruptions without comedones or aggravate pre existing acne vulgaris *Halogen acne is usually more exuberant than acne vulgaris* Occupational acne often affects the forearms and thighs as much as the face

Rosacea usually occurs in an older age group than acne vulgaris but occasionally starts in the teens *The lesions involve an oval area of the centre of the face* They are erythemato papular and pustular but there are no comedones though scars of *previous acne may remain* There is *marked vasolability and the face is bright red* not the muddy colour of acne vulgaris

Treatment depends on control of the primary cause and of the aggravating factors The primary cause is a relative excess of *androgens in relation to œstrogens* The aggravating factors are numerous They include a familial predisposition dietetic errors certain drugs contact irritants imperfect hygiene and insufficient weathering and emotional tension related in particular to conflicts with parental authority and difficulty in psychosexual adjustment to adult life the acne sufferer often being somewhat retarded in this respect while intellectually adequate and physically mature

Treatment aims at correcting the endocrine imbalance so as to diminish sebaceous over activity and attaining and retaining patency of the pilosebaceous follicles

It is inadvisable to use œstrogens in the male in the dosage necessary to give a good result the emasculating effects that also result are undesirable Emotional changes and gynæcomastia may result In females œstrogens may justifiably be given if there is oligomenorrhœa irregular menstruation male type hirsutism or marked aggravation of the acne before the menses but it is inadvisable to use them even in these circumstances for the first few years after the menarche it is better to allow time for menstruation to acquire a regular rhythm

When prescribing œstrogens for acne the patient should be asked to estimate the expected first day of the next menstrual period and to begin the treatment 10 days *before this date and continue until menstruation begins In this way there is no* interference with ovulation If menstruation is markedly irregular it is not possible to adopt this *procedure* and the patient *is instructed to start treatment a fortnight* after the last day of the previous menstrual flow and continue for a fortnight or until the next period begins whichever is the shorter This treatment is continued for 3 to 6 months

The diet should be high in protein and vitamin content Excess of fats and carbohydrates must be avoided In particular chocolate cocoa cream pastries and cheeses are liable to aggravate acne

Bromides and iodides have in the past been responsible for much aggravation of acne but they are in less common use to day Other drugs for example aspirin occasionally aggravate acne

The skin should be washed at least twice a day with a good toilet soap Medicated soaps are best avoided If cosmetics are used they should be of the lotion type not creams The patient should be discouraged from experimenting with local applications Irritant or sensitising substances incorporated in a base capable of mixing well with fat and water may cause a severe chemical folliculitis Similarly exposure

ACNE VULGARIS

A papular condition due to hyperkeratotic plugging of the pilosebaceous follicles combined with hyperplasia of the sebaceous glands

Ætiology and Pathology—Acne is brought about by an imbalance between androgenic and œstrogenic hormones In the male, an excess of testosterone is responsible, in the female, an excess of progesterone is believed to be the cause In either case there is a resultant sebaceous hyperplasia and a diffuse hyperkeratosis which at the pilosebaceous orifices particularly at the openings of glabrous hairs causes obstruction to the flow of sebum A blackhead (comedo) is an hyperkeratotic follicular plug This follicular obstruction leads to inflammatory changes (papular acne) the keratin and sebum having a foreign body effect This inflammation may end in resolution or in suppuration (pustular acne) in either case the end result is some degree of fibrosis The pus is usually sterile and if the suppuration is deep it may form cystic swellings in the hypoderm (acne conglobata) Burrowing tracks may form lined with epidermis and there may be small epidermal bridges and tunnels with several openings

Severe acne tends to end in keloid formation, particularly at the nucha over the sternum and, with smaller lesions on the face and neck (acne keloid)

In addition to the cystic swellings already mentioned, epidermal cysts of pinhead size may be interspersed amongst the acne lesions (' white ' acne)

There is no evidence that the acne bacillus is the cause of acne This organism is, like the pityrosporon of Malassez and the *Staphylococcus saprophyticus*, a secondary invader of the truly seborrhœic skin Some comedones contain an acarus, the demodex folliculorum Most acne lesions are sterile but sometimes there is a heavy secondary infection with staphylococci (acne sycosis) in these circumstances the pustules are notably more superficial and contain liquid pus as opposed to the cheesy contents of many acne pustules

Clinical Picture—Slight degrees of acne at puberty are so common as to be regarded as physiological It usually begins at about 12 to 14 years of age and diminishes in severity at 18 to 20 In girls it often coincides with the menarche Occasionally acne persists into adult life and may even last throughout life As a rule, males are more severely affected than females

Acne affects the face and neck, the upper trunk and to a lesser degree the lumbar region buttocks and limbs

A comedo (blackhead) (acne punctata) is a black or dirty grey pinhead sized hard speck at a pilosebaceous orifice In an uncomplicated comedo there is no redness or swelling but when this occurs an acne papule results acuminate firm and comedo topped liquefactive changes lead to a deep seated pustule This may resorb or break spontaneously or be broken by the patient s manipulations, and a funnel like, depressed scar results Lesions of acne conglobata are obtuse, dome shaped bluish-grey nodules It is not unusual to see comedones papules pustules small epidermal cysts cystic swellings and scars, often keloidal in the same patient

The complexion in acne is greasy and muddy, the thickened epidermis diminishing transmission of colour from blood flowing in the superficial vessels of the dermis Visibly enlarged patulous follicles are present and excessive sebum formation may be visible especially at the alæ nasi There may be an increase of dandruff but this is by no means the rule The acne patient of either sex is usually somewhat hirsute and in females the pubic hair often has a masculine distribution There may also be hyperidrosis

Course and Prognosis—Acne vulgaris usually clears up or improves considerably after the teens If it does not some cause can usually be found (see below) A variable amount of scarring is inevitable except in the milder forms

the first few days after birth It has been suggested that these are due to androgenic hormonal influences (progesterone) from the mother

(2) The use of camphorated oil olive oil or tallow as an embrocation may cause an acneiform eruption on the face or chest (grouped comedones)

(3) Excessive and occlusive wrapping up of the child s body may by increasing sweating on the face cause some inflamed follicular papules

(4) Occasionally cod liver oil given by mouth causes acneiform papules

(5) Unilateral nævi consisting of grouped comedones occur

(6) Adrenocortical neoplasms are accompanied by acne as is the administration of corticotrophin or cortisone

ROSACEA (ACNE ROSACEA) (see p 1207)

ACNE NECROTICA (ACNE VARIOLIFORMIS)

This is a relatively rare inflammatory condition of the follicles with discrete papulo pustulation on the forehead scalp and temples going on to necrosis and scarring

Ætiology and Pathology—The condition is a folliculitis due to coagulase-positive staphylococci Histological changes of acne vulgaris are present with the addition of œdema and an inflammatory infiltrate leading to superficial follicular necrosis

Clinical Picture—The patients are usually middle aged men but women may also be affected Near the hair margin across the forehead at the temples and on the neck are discrete brownish papules pustules and scabs with depressed scars It may also appear on the face limbs and trunk There may be much itching and picking of the lesions which are present in all stages at the same time Affected individuals usually show evidence of the seborrhœic state

Course and Prognosis—The condition tends to persist indefinitely and to relapse after treatment is stopped

Diagnosis is from seborrhœic folliculitis acne vulgaris syphilis and variola The duration distribution itching and polymorphic lesions suggest the correct diagnosis Seborrhœic folliculitis leaves little or no scarring

Treatment which is usually effective consists of the application of the appropriate antibiotic depending on sensitivity tests The associated seborrhœic state must receive attention Other remedies sometimes used include zinc and copper lotion potassium sulphate lotion Vioform cream or Quinolor ointment

ACNE URTICATA

This is an eruption of small wheals on the scalp face or elsewhere Excoriations often result (see Urticaria)

ACNE SCROFULOSORUM (see Cutaneous Tuberculosis)

ACNE AGMINATA (ACNITIS LUPOID PAPULAR TUBERCULIDE)

Clinical Picture—This is a papular eruption affecting the forehead eyelids nose and cheeks and sometimes the penis The papules are yellow and translucent giving a lupoid apple jelly appearance on diascopy The lesions are all at the same stage of development Necrosis subsequently occurs and when the scabs separate depressed scars are left

Ætiology and Pathology—The condition has been thought to be a tuberculide but the Mantoux reaction may show normergy or hypoergy to tuberculin and it has been suggested that the condition is a viride

to brine, pitch tar, organic chlorine compounds, paraffin or petroleum oils (cutting oils, greases, waxes) may cause or aggravate acne

Woollen underclothing should not be worn next to the skin

The acne patient should be encouraged to take outdoor exercise in all weathers The fine exfoliation that follows sun bathing is beneficial as is the flush that follows exposure to wind and rain

Infected acne may be improved with appropriate topical antibiotics and by staphylococcal toxoid injections

In those cases of acne in which emotional factors are relevant the control is difficult and psychiatric assistance is sometimes necessary The acne patient should be encouraged to mix with other young people and to have wide social activities

Local treatment —This mainly aims at bringing about a fine peeling of the skin For this purpose a weekly second degree exposure to ultra violet irradiation (enough to cause a branny peeling) is most helpful The carbon arc lamp is most efficacious but, if not available, good results can usually be obtained with the mercury vapour lamp Before giving either of these treatments to acne involving the trunk it is advisable to make a radiographic examination of the chest in order to exclude the presence of an asymptomatic focus of tuberculosis which might be activated by this treatment For more severe acne induratum, a third degree exposure (to cause coarse peeling) may be necessary

Medicaments for local application in acne should either be lotions or pastes Creams and ointments are likely to prove harmful Zinc sulphate lotion compound sulphur lotion and calamine lotion with 2 per cent of sulphur are all useful A flesh tinted paste will serve the double purpose of treatment and camouflage Resorcin and sulphur paste (tinted) is of reasonable cosmetic quality

The liberal use of soap and water and the avoidance of cream cosmetics should go hand in hand with the above treatment Many patients with acne vulgaris manipulate the lesions by squeezing in the hope that contents will be expressed and resolution hastened This undesirable habit is the cause of much funnel like scarring of the follicular orifices Manipulation should be limited to brisk friction with a face flannel or a soft nail brush

Carbon dioxide snow applications (1 to 3 seconds) to larger nodules are useful by bringing about a coarse peeling

Cystic swellings need puncture before giving this treatment

X-rays can be used with a view to bringing about some involution of the sebaceous glands in severe and resistant acne particularly if it is localised An exposure of 100 to 150 r repeated weekly up to a total of 600 r is a reasonable dosage Any cystic swellings should be punctured before this treatment is given On no account should more than two of such courses be given (total 1200 r) because above this level post irradiation atrophic changes are likely to occur

ACNE EXCORIÉE DES JEUNES FILLES

In this condition excoriations dominate the picture Comedones are usually but not always present and numerous excoriated papules and scars particularly at the forehead temples cheeks and chin

Acne excoriee indicates the presence of an emotional conflict and calls for psychological investigation and treatment Local treatment is ineffective unless the urge to pick the spots has been removed The best application is a flesh tinted paste for example titanium dioxide paste

ACNE IN INFANCY

This is rare but may occur in the following ways

(1) Newborn babies often have numerous small papulo-pustules on the face for

mentation The mouth is not affected Nikolsky s sign is negative and the Tzanck test shows blood cells particularly eosinophils but no acantholytic epidermal cells The administration of potassium iodide by mouth or a patch test with potassium iodide causes an increased vesiculation There is usually eosinophilia The general health suffers little if at all apart from the disturbing effects of the intense itching

Course and Prognosis—Dermatitis herpetiformis may persist for several years, with fluctuations after which it sometimes gets gradually milder and finally disappears Its onset and course is controlled to some extent by any emotional stresses to which the sufferer may be exposed The prognosis as regards life is good

Diagnosis is from other bullous eruptions erythema multiforme urticaria prurigo general pruritus and infestations The other bullous eruptions are in no way so itchy as dermatitis herpetiformis Pemphigus often affects the mouth and leaves extensive raw areas the patient being gravely ill In erythema multiforme bullosum itching is less the blisters are always within erythematous areas and excoriations are absent Urticaria is evanescent though possibly recurrent In prurigo lichenification and excoriation are the predominant features and vesicles are never seen In pruritus there may be scratch marks and excoriations but no vesicles In infestations there are scratch marks on the shoulders and around the waist and an examination of the scalp and underclothes should disclose the cause

Treatment—Sulphapyridine (but no other sulphonamide) acts as a specific in dermatitis herpetiformis with very few exceptions A dose of 1 g three times a day controls the itching and the development of vesicles within 24 to 36 hours After this the dose is reduced until the optimal level is found at which the symptoms are just controlled The addition of nicotinic acid 50 mg up to three times a day may enable a smaller dosage of sulphapyridine to be used Periodic total and differential white cell counts should be performed to detect drug leucopenia If the white cell count remains around 6000 per c mm the drug may be continued indefinitely without harm If the white cell count drops to 4000 per c mm or lower it is advisable to suspend the sulphapyridine for a time and to replace it by some other form of treatment Dapsone 50 mg daily is often as effective as sulphapyridine When taking this drug the patient should also be given ferrous sulphate tablets and vitamin B Fowler s solution in a dosage of 3 to 5 minims three times a day is often effective but it is best to revert to sulphapyridine or to dapsone as soon as the white cell count permits because of the long term toxic effects that may result from the use of Fowler s solution

Antibiotics sometimes help and sometimes aggravate dermatitis herpetiformis and their trial is only justified when other means fail When they are used the patient should be kept under close observation so that treatment can be suspended at once if untoward symptoms develop

General ultra violet irradiation sometimes seems to relieve the itching Phenobarbitone is also useful in the interim between courses of sulphapyridine or dapsone but bromides are contraindicated because like iodides they may aggravate the condition

Local applications that may help include 1 per cent. of phenol in calamine lotion and 2 per cent of solution of coal tar in Lassar s paste Sodium bicarbonate baths (4 oz in 25 gallons) may prove soothing

HERPES GESTATIONIS

This is a form of dermatitis herpetiformis affecting pregnant women usually in the third trimester It may recur in subsequent pregnancies Relief usually but not always occurs after delivery

Treatment is complicated in that both sulphapyridine and Fowler s solution are undesirable because of the pregnancy Dapsone may be used or recourse had to

Histologically there is a tuberculoid pattern with central caseation and a surrounding inflammatory infiltrate

Course and Prognosis —The lesions are resistant to treatment by antituberculous drugs but tend to undergo spontaneous resolution after several months leaving scars

Treatment is supportive and nonspecific

CHRONIC BULLOUS ERUPTIONS

The chronic bullous eruptions are a group of reactions of unknown cause, the recognition of which is nevertheless most important because of their differing prognoses and treatments In their differentiation reliance has to be placed on the history and physical signs and in particular on the presence or absence of Nikolsky s sign The Tzanck test also is a simple and useful diagnostic procedure

Nikolsky's sign can be demonstrated in two ways If there is an intact bulla an attempt is made to push this along in the skin with one thumb, while anchoring the adjacent skin with the other hand Nikolsky s sign is positive if the bulla can be moved along in the skin The other method is to apply tangential stress to the apparently normal skin The skin over the collarbone or tibia is anchored with the left thumb and forcible lateral pressure is applied with the right thumb The sliding off of the superficial layers indicates a positive Nikolsky s sign The sign is positive in pemphigus vulgaris pemphigus vegetans pemphigus foliaceus pemphigus erythematodes, pemphigoid benign familial pemphigus and epidermolysis bullosa It is negative in dermatitis herpetiformis and in erythema multiforme

The Tzanck test is performed by removing the roof and scraping the floor of a bulla The material thus obtained is spread on a slide stained and examined under the microscope for acantholytic cells (epidermal cells which have lost their prickles) Alternatively, lateral stress may be applied to a portion of skin and biopsy subsequently performed The Tzanck test is positive if slit like clefts are apparent within the epidermis and if within them single acantholytic cells or groups of them are seen

DERMATITIS HERPETIFORMIS (DUHRING S DISEASE)

Dermatitis herpetiformis is a disorder in which grouped itchy vesicles and small bullæ arise on normal or reddened skin

Ætiology and Pathology —The cause is unknown a virus cause is suspected It is most common between the ages of 30 and 50 and is rare in early adult life and in childhood There is an excessive susceptibility to the blister producing influences of potassium iodide both by its ingestion and by its topical application

Histologically the bullæ are at the epidermo dermal junction they tend to be oval in shape when seen in sections they contain blood cells with many eosinophils but no abnormal epidermal cells There is an infiltrate of inflammatory cells around the bullæ The overlying epidermis shows evidence of scratching with loss of tissue a nonspecific infiltrate including some eosinophils and perhaps some patchy spongiosis and irregular excesses of melanin pigmentation

Clinical Picture —The patient complains of an intensely itchy eruption which though often widespread shows a marked tendency to grouping The sites most commonly affected are the shoulder blades the elbows the buttocks and genitalia and the knees but no area is immune and the face may be involved The eruption is polymorphic The individual lesions are flaccid or tense millet seed sized vesicles arising from skin which may be apparently normal or reddened Owing to the severe itching it is rare to see many intact vesicles and the physical signs usually consist more of excoriated and scabbed erythematous papules erosions scars and patchy pig

PEMPHIGUS FOLIACEUS AND PEMPHIGUS ERYTHEMATODES

These are forms of pemphigus in which exfoliation is the most prominent feature bullæ rarely being seen because they are superficial and easily ruptured The course is irregular but usually somewhat more benign than pemphigus vulgaris Remissions and relapses occur It is uncertain whether the condition can develop into pemphigus vulgaris

Pathology—The cellular disruption is at the granular cell layer The overlying cells become detached with the result that on section blisters are not seen but the granular layer is either exposed to the surfaced or covered by loosely attached groups of horny cells

Clinical Picture and Differential Diagnosis—In pemphigus foliaceus the picture resembles erythroderma perhaps with some econdary infection but Nikolsky s sign is positive in pemphigus foliaceus and negative in erythroderma There is cru ting and a tendency to wartiness with pigmentation In pemphigus erythema todes (Senear Usher syndrome) the condition resembles infective dermatitis because the superficial lesions become secondarily infected or with single or few lesions on the face there may be a resemblance to lupus erythematosus but the moistness of the lesions and the looseness of the overlying skin cast doubt on the diagnosis of lupus erythematosus

Nikolsky's *sign is positive There is a variable degree of general disability*

Course and Prognosis—The natural course is a slow worsening with remissions *and recrudescences and a fatal outcome usually from some infective complication*

Treatment is as for pemphigus vulgaris (*q v*) with corticotrophin or cortisone and antibiotics Blood or plasma transfusions are usually unnecessary because the loss of body fluid is much less than in pemphigus vulgaris When the secondary infection is under control calamine liniment may be applied

SENILE DERMATITIS HERPETIFORMIS OR PEMPHIGOID

An eruption of tense bullæ often with considerable erythema around with much itching occurring in the seventh or eighth decades and sometimes ending fatally

Ætiology and Pathology—The cause is unknown

The bullæ are at the epidermo dermal junction and contain blood cells including many eosinophils They are oval when seen in sectional view

Clinical Picture—Large tense bullæ some containing straw coloured fluid others containing blood or even pus are present in the skin particularly on the limbs The mucous membranes of the mouth are sometimes affected with blisters and raw areas but the vermilion surfaces of the lips escape There is intense itching but less constitutional upset than in pemphigus vulgaris Nikolsky s sign is positive but the Tzanck test shows eosinophil and other blood cells but no acantholytic cells The bullæ do not rupture easily and if they are broken they tend to heal and do not spread spontaneously as in pemphigus vulgaris Small white cysts (milia) may form in the process of healing Serum protein and electrolytic changes are minimal

Course and Prognosis—The natural course is chronicity with occasional re missions The prolonged course with loss of sleep from itching and secondary infection may lead to death

Diagnosis from erythema multiforme may be difficult In erythema multiforme Nikolsky s sign is negative and spontaneous resolution occurs in a few days or weeks

Pemphigus vulgaris differs from pemphigoid by its more flaccid and easily rup tured blisters with severe involvement of the mouth and lips and a heavy loss of electrolytes and protein Senile dermatitis herpetiformis differs from dermatitis herpetiformis in its larger tense bullæ positive Nikolsky s sign muco al involvement and more serious course

Treatment is as for pemphigus (*q v*) with corticotrophin or cortisone After

symptomatic relief with phenobarbitone or promethazine hydrochloride until the time of delivery

PEMPHIGUS VULGARIS

A bullous disorder with an irregular course, often ending fatally In the flexures it forms vegetations (pemphigus vegetans)

Ætiology and Pathology—The cause is unknown essentially there is a lack of cohesion between the epidermal prickle cells The malady usually occurs after the age of 40 and Jews are especially liable to be affected

Histologically there are slit like clefts within the stratum mucosum just above the stratum germinatum and acantholytic cells are seen within the clefts In section the extremities of the clefts are acute as opposed to the obtuse clefts seen in dermatitis herpetiformis

Clinical Picture—Large and small flaccid bullæ are present on seemingly normal areas of skin Many ruptured bullæ are seen with extensive red raw areas from which considerable loss of serum occurs These raw areas tend to spread peripherally and show no tendency to heal spontaneously Itching is slight or absent The general health steadily deteriorates Secondary infection is common particularly in the flexures where malodorous soft moist, warty elevations or vegetations develop The malady may at first be localised but ultimately the whole surface may be patchily affected At pressure sites such as the elbows scapulæ sacrum buttocks and heels deep sores are liable to form The mucous membranes of the mouth vulva and penis are usually affected with considerable distress to the patient The vermilion surface of the lips and the mucous surfaces of the tongue cheeks and roof and floor of the mouth are extensively denuded giving an appearance of rawness covered by a white exudate and with loose tags of epidermis at the edges Nikolsky s sign and the Tzanck test are positive The serum proteins are often markedly diminished (particularly the albumin) owing to loss of body fluids from the extensive oozing raw areas There is severe hypochromic anæmia and salt depletion Sodium chloride and calcium depletion also occur but the serum potassium may be raised Ulceration of the mouth interferes with swallowing and may further weaken the patient from nutritional deficiency

Course and Prognosis—The natural course is one of worsening with occasional spontaneous remissions usually followed by fresh outbreaks of increased severity ultimately leading to death from general infection and pneumonia complicated by protein and electrolytic deficiencies This gloomy picture has been greatly improved since the introduction of corticotrophin and cortisone

Diagnosis from other bullous eruptions is made with certainty from a consideration of the physical signs and the results of the Tzanck test

Treatment—The first essential is nursing care of the highest standard Corticotrophin intramuscularly in a dose of up to 50 mg every 6 hours usually leads to a remission The dose is then reduced to the minimal maintenance level The mucous lesions do not respond so well as the skin lesions The latter heal well with deep pigmentation When the patient becomes ambulant cortisone orally is more convenient in the smallest dose consistent with relief This treatment may have to be combined with an antibiotic to combat any infection that is present

Whole blood or plasma transfusions are useful but they cannot in themselves replace the deficiency of albumin and an adequate diet high in protein content, must be given Nasal feeding may be necessary The mouth must be kept as clean as possible with normal saline or glycerin and thymol

For the infected skin chlortetracycline ointment is useful and when the lesions are clean tulle gras applications are comforting Some prefer a powder bed the patient lying in sheets heavily sprinkled with boric talc powder

bear no relation to treatment seasons or any other known cause Regarding length of life the prognosis is good

Diagnosis—From infective dermatitis the condition is recognised by its chronicity and by the characteristic histology

Treatment—There is no effective treatment The lesions should be covered with calamine liniment to which may be added 1 per cent of ichthammol or 0 1 per cent of pyrogallol Antibiotics may be used for any serious degree of secondary infection Clothing should be soft and smooth and loosely fitting A dusting powder containing zinc oxide and zinc stearate may by giving slip help to prevent the development of lesions

EPIDERMOLYSIS BULLOSA

This inherited malady occurs in two forms the simple and the dystrophic The skin is vulnerable to minor traumata and to sunlight

Ætiology and Pathology—The cause is a genetic fault

The histology differs in the two forms In the simple form clefts occur in the epidermis but in the dystrophic form they are in the dermis and scarring and loss of tissue often result with the formation of epidermal cysts

Clinical Picture—In the simple form the infant is noticed to blister easily at sites of trauma especially the hands and feet elbows and knees shoulder and buttocks In milder forms this phenomenon may not be apparent until later in life and serious blistering may only be noticed when the individual starts soldiering

In the dystrophic form the disruption of the dermis is so severe that scarring and deformity often result In particular the nails are likely to be shed and the new nails are dystrophic and irregular Ectodermal defects of the hair and teeth may also be present and erosions occur on mucous surfaces as well as on the skin

Course and Prognosis—The course is uninterrupted and there are no remissions The condition interferes considerably with the patient s activities

Treatment—There is no effective treatment The aim should be the avoidance of traumata likely to cause blistering Special care is necessary in the choice of clothing particularly shoes and the sufferer cannot join in many of the activities usually indulged in by the young Blisters should be dealt with by careful puncture and antibiotics applied if infection occurs

SCLERODERMA AND ALLIED CONDITIONS

Sclerosis is a condition in which collagen undergoes inflammatory fibrotic changes proceeding to a terminal atrophic phase If the skin seems to be the only organ affected the term scleroderma is appropriate but when one or more internal organs are affected the term systemic sclerosis is more suitable

CIRCUMSCRIBED SCLERODERMA

Clinical Picture—Circumscribed scleroderma (morphœa) presents as an itchy round oval or irregular firm pale or skin coloured smooth candle wax like plaque with a lilac halo There may be one or several of such lesions and when numerous there is a marked tendency to symmetry A variant is morphœa guttata

Ætiology and Pathology—The cause is unknown Adults are affected more than children and women more than men

Histologically there is an early inflammatory stage in which the collagen bundles are swollen homogeneous and separated by œdema the fat and elastic tissue degenerate or destroyed There is a lymphocytic infiltrate Later the infiltrate diminishes and the collagen of the dermis is seen to be thickened and condensed The blood

obtaining a remission with intramuscular corticotrophin the ambulant patient can be treated with gradually reduced doses of cortisone until in some cases the drug can be withdrawn and recurrence does not occur In others mild or severe recrudescences necessitate further treatment with corticotrophin Local treatment consists of aseptic puncture and collapse of the large tense bullæ and suitable antibiotic or emollient dressings

BENIGN PEMPHIGUS OF THE MUCOUS MEMBRANES (OCULAR PEMPHIGUS)

A bullous eruption in which the eyes and mouth are mostly affected and the skin slightly or not at all

Pathology—The blisters are at the epidermo dermal junction there is no acanthosis but a heavy inflammatory infiltrate and later fibrosis

Clinical Picture—The conjunctivæ become inflamed and fibrous adhesions form between the palpebral and ocular surfaces or between the upper and lower palpebral surfaces The conjunctival sacs become shallow and the palpebral fissures narrow and the eyeballs limited in their range of movement The cornea may be damaged by entropion xerosis or pannus with loss of vision Vesicles form in the mouth and by coalescence form large red denuded areas The vermilion surface of the lips escapes but the mouth may be narrowed by adhesions Lesions may form anywhere in the mouth nose or throat in the œsophagus causing dysphagia on the glans penis or prepuce causing phimosis or on the vulva or vagina causing narrowing The skin of the scalp or face is affected in about half the patients with erythema flaccid bullæ and erosions going on to scarring

Course and Prognosis—The malady is slowly progressive with remissions and recurrences

Diagnosis is from pemphigus vulgaris pemphigoid, severe erythema multiforme and aphthosis including Behcet s syndrome

In pemphigus the lesions are in the epidermis and the vermilion surfaces of the lips are often affected In pemphigoid the eyes usually escape and the skin lesions which predominate consist of large tense bullæ In severe erythema multiforme the onset is abrupt, the patient is a child or young adult and the skin involvement is extensive In Behcet s disease there are erosions and ulceration of the eyes mouth and genitalia often with some destruction of tissue

Treatment—Cortisone eye drops are invaluable and corticotrophin or cortisone may help to alleviate the other manifestations For the mouth a bland mouth wash should be prescribed

BENIGN FAMILIAL PEMPHIGUS (OF GOUGEROT AND HAILEY HAILEY)

This is a chronic erosive condition of friction sites occurring in many members of the same family benign in its course and with a tendency to spontaneous remissions

Ætiology and Pathology—This inherited malady is possibly a bullous variant of dyskeratosis follicularis

Histologically there is acantholysis the detachment occurring in the stratum mucosum

Clinical Picture—Benign pemphigus resembles a very resistant infective dermatitis The lesions are flexural or at sites of friction such as the *collar line* axillary folds and groins and they consist of erosions covered by greasy *scaling* The patient complains of a tendency to chafing of the skin at sites of pressure from clothes and there is a history of a similar condition in other members of the family

Course and Prognosis—The course is chronic with occasional remissions which

bear no relation to treatment seasons or any other known cause Regarding length of life the prognosis is good

Diagnosis —From infective dermatitis the condition is recognised by its chronicity and by the characteristic histology

Treatment —There is no effective treatment The lesions should be covered with calamine liniment to which may be added 1 per cent of ichthammol or 0 1 per cent of pyrogallol Antibiotics may be used for any serious degree of secondary infection Clothing should be soft and smooth and loosely fitting A dusting powder containing zinc oxide and zinc stearate may by giving slip help to prevent the development of lesions

EPIDERMOLYSIS BULLOSA

This inherited malady occurs in two forms the simple and the dystrophic The skin is vulnerable to minor traumata and to sunlight

Ætiology and Pathology —The cause is a genetic fault

The histology differs in the two forms In the simple form clefts occur in the epidermis but in the dystrophic form they are in the dermis and scarring and loss of tissue often result with the formation of epidermal cysts

Clinical Picture —In the simple form the infant is noticed to blister easily at sites of trauma especially the hands and feet elbows and knees shoulder and buttocks In milder forms this phenomenon may not be apparent until later in life and serious blistering may only be noticed when the individual starts soldiering

In the dystrophic form the disruption of the dermis is so severe that scarring and deformity often result In particular the nails are likely to be shed and the new nails are dystrophic and irregular Ectodermal defects of the hair and teeth may also be present and erosions occur on mucous surfaces as well as on the skin

Course and Prognosis —The course is uninterrupted and there are no remissions The condition interferes considerably with the patient s activities

Treatment —There is no effective treatment The aim should be the avoidance of traumata likely to cause blistering Special care is necessary in the choice of clothing particularly shoes and the sufferer cannot join in many of the activities usually indulged in by the young Blisters should be dealt with by careful puncture and antibiotics applied if infection occurs

SCLERODERMA AND ALLIED CONDITIONS

Sclerosis is a condition in which collagen undergoes inflammatory fibrotic changes proceeding to a terminal atrophic phase If the skin seems to be the only organ affected the term scleroderma is appropriate but when one or more internal organs are affected the term systemic sclerosis is more suitable

CIRCUMSCRIBED SCLERODERMA

Clinical Picture —Circumscribed scleroderma (morphœa) presents as an itchy round oval or irregular firm pale or skin coloured smooth candle wax like plaque with a lilac halo There may be one or several of such lesions and when numerous there is a marked tendency to symmetry A variant is morphœa guttata

Ætiology and Pathology —The cause is unknown Adults are affected more than children and women more than men

Histologically there is an early inflammatory stage in which the collagen bundles are swollen homogeneous and separated by œdema the fat and elastic tissue degenerate or destroyed There is a lymphocytic infiltrate Later the infiltrate diminishes and the collagen of the dermis is seen to be thickened and condensed The blood

obtaining a remission with intramuscular corticotrophin the ambulant patient can be treated with gradually reduced doses of cortisone until in some cases the drug can be withdrawn and recurrence does not occur In others mild or severe recrudescences necessitate further treatment with corticotrophin Local treatment consists of aseptic puncture and collapse of the large tense bullæ and suitable antibiotic or emollient dressings

BENIGN PEMPHIGUS OF THE MUCOUS MEMBRANES (OCULAR PEMPHIGUS)

A bullous eruption in which the eyes and mouth are mostly affected and the skin slightly or not at all

Pathology—The blisters are at the epidermo dermal junction there is no acanthosis but a heavy inflammatory infiltrate and later fibrosis

Clinical Picture—The conjunctivæ become inflamed and fibrous adhesions form between the palpebral and ocular surfaces or between the upper and lower palpebral surfaces The conjunctival sacs become shallow and the palpebral fissures narrow and the eyeballs limited in their range of movement The cornea may be damaged by entropion xerosis or pannus with loss of vision Vesicles form in the mouth and by coalescence form large red, denuded areas The vermilion surface of the lips escapes but the mouth may be narrowed by adhesions Lesions may form anywhere in the mouth nose or throat in the œsophagus, causing dysphagia, on the glans penis or prepuce causing phimosis or on the vulva or vagina causing narrowing The skin of the scalp or face is affected in about half the patients with erythema flaccid bullæ and erosions going on to scarring

Course and Prognosis—The malady is slowly progressive with remissions and recurrences

Diagnosis is from pemphigus vulgaris pemphigoid severe erythema multiforme and aphthosis including Behcet s syndrome

In pemphigus the lesions are in the epidermis and the vermilion surfaces of the lips are often affected In pemphigoid the eyes usually escape and the skin lesions which predominate consist of large tense bullæ In severe erythema multiforme the onset is abrupt the patient is a child or young adult and the skin involvement is extensive In Behcet s disease there are erosions and ulceration of the eyes mouth and genitalia often with some destruction of tissue

Treatment—Cortisone eye drops are invaluable and corticotrophin or cortisone may help to alleviate the other manifestations For the mouth a bland mouth wash should be prescribed

BENIGN FAMILIAL PEMPHIGUS (OF GOUGEROT AND HAILEY HAILEY)

This is a chronic erosive condition of friction sites occurring in many members of the same family benign in its course and with a tendency to spontaneous remissions

Ætiology and Pathology—This inherited malady is possibly a bullous variant of dyskeratosis follicularis

Histologically there is acantholysis the detachment occurring in the stratum mucosum

Clinical Picture—Benign pemphigus resembles a very resistant infective dermatitis The lesions are flexural or at sites of friction such as the collar line axillary folds and groins and they consist of erosions covered by greasy scaling The patient complains of a tendency to chafing of the skin at sites of pressure from clothes and there is a history of a similar condition in other members of the family

Course and Prognosis—The course is chronic with occasional remissions which

sorption of the tufts of the terminal phalanges and there may be subcutaneous deposits of calcium Radiography of the chest may show reticulation due to pulmonary fibrosis or areas of pneumonia due to aspiration from the œsophagus there may be hypertrophy of the right side of the heart and the electrocardiogram may be abnormal Radiological investigation of the gastro intestinal tract is often abnormal in the œsophagus fibrous stricture dilatation absence of peristalsis and hiatus hernia have been described diminished peristalsis dilatation and diverticula have been seen in the small and large intestine

Course and Prognosis—Rarely there is rapid evolution of the disease with death in a few months More usually the disease is slowly progressive without remissions with increasing disability from Raynaud s phenomenon painful indolent fissures of the fingers limitation of movement of the fingers wrists elbows and shoulders increasing dyspnœa and perhaps dysphagia Death occurs in 5 to 10 years from inhalation broncho pneumonia heart failure or renal failure The disease may become arrested leaving the patient with residual deformities due to fibrosis

Diagnosis—In the early stages the aching and swelling of the fingers may suggest rheumatoid arthritis and Raynaud s phenomenon has to be distinguished from Raynaud s disease

Pulmonary involvement may be confused with bronchiectasis pigmentation with Addison s disease and œsophageal involvement with cardiospasm

Treatment—Local applications such as compound tincture of benzoin in lanoli may be necessary for the painful fissures of the fingers Raynaud s phenomenon should be treated in the same way as Raynaud s disease if it is severe cervical sympathectomy is justifiable although it has no influence on the course of the disease

Corticotrophin and cortisone may produce a temporary improvement in the œdema tous stage but has no effect on the fibrotic lesions and it does not appear to have any effect on the ultimate prognosis

DERMATOMYOSITIS

Ætiology—The cause is unknown Males and females are equally affected the disease usually starts between the ages of 20 and 40 Some cases have been associated with carcinoma of the lung and other organs

Pathology—In the skeletal muscles there is parenchymal degeneration with an interstitial inflammatory reaction there is proliferation of nuclei of the muscle fibres and loss of the normal cross striations in the interstitial tissue there is a variable infiltration with lymphocytes histiocytes plasma cells and fibroblasts Later there is replacement fibrosis of the muscles Similar changes may be found in the myocardium In the dermis the collagen fibres may be swollen and homogeneous and there is a perivascular infiltration with lymphocytes and other cells

Clinical Picture—The onset is usually insidious but may be acute The early symptoms are muscular pain and weakness or subcutaneous œdema and erythema Occasionally Raynaud s phenomenon is the first symptom There may be generalised involvement of skeletal muscles from the start or the disease may begin in the limbs and spread to the trunk The neck shoulder and pelvic girdle muscles are most affected The muscles are painful tender and weak they feel indurated and later hard and fibrous

There is limitation of movement because of inability of the muscles to stretch The tendon jerks are diminished or absent Dysphagia dysphonia and dyspnœa are common from involvement of the pharynx larynx intercostal muscles and dia phragm Facial weakness and diplopia may be found

Skin changes are rarely absent and may be persistent or transient The com monest change is a firm subcutaneous œdema which may be generalised but is usually confined to the face and limbs There may be a diffuse mottled purple

vessels of the dermis and hypoderm show similar changes The pilosebaceous follicles disappear but the sweat glands usually perist

Course and Prognosis—Clinically the lesions may cease to itch and end in moderately atrophic plaques This form, whether solitary or multiple seems to be unrelated to systemic sclerosis In the severest forms bullæ may develop owing to lymph stasis

Diagnosis is from lichen sclerosus et atrophicus, vitiligo paraffinoma, leprosy (*q v*)

Treatment—There is no specific treatment A bland application such as unguentum aquosum to make up for the secondary sebaceous deficiency is often comforting Sedatives may be required for severe itching

SYSTEMIC SCLEROSIS

Ætiology—The cause is unknown The disease occurs almost exclusively in women and usually starts before the age of 40

Pathology—The changes in the skin are similar to those in circumscribed scleroderma In the gut there are areas where the muscularis is replaced by fibrous tissue There may be invasion of the myocardium and skeletal muscles by connective tissue with atrophy of muscle fibres The alveolar walls in the lungs may be infiltrated by fibrous tissue, and the capillary loops of the kidney often show fibrinoid degeneration

Clinical Picture—This is usually a very slowly progressive disease in which the early manifestations are due to involvement of the skin and subcutaneous tissue later there is often evidence of visceral involvement The earliest changes in the skin are thickening and non pitting œdema but this stage may be absent Later there is induration so that the skin cannot be pinched up and finally there is atrophy involving also the subcutaneous tissue when the skin is bound down to the deeper structures

The onset is usually insidious, starting in the hands with Raynaud s phenomenon or aching stiffness and swelling of the fingers If Raynaud s phenomenon is the first symptom it is usually followed in a few weeks by swelling and limitation of movement but occasionally there is an interval of many years There is a gradual extension over several years to the forearms face and chest Later the feet and legs may be affected and rarely the whole body The onset is sometimes more rapid the evolution taking about a year Rarely the disease may start in the face and trunk sparing the hands

The fingers are pointed with wasting of the pulps of the terminal phalanges the nails curved the skin is shiny thin and tightly bound to the deep fascia causing limitation of movement there may be painful fissures and ulcers and areas of superficial gangrene The face is expressionless with loss of the natural creases the nose is pointed, the mouth pinched and the lips thin and puckered The skin of the limbs and trunk is thickened and difficult to pinch up There is limitation of movement of the joints within the affected area There is often diffuse dark brown pigmentation of the skin and sometimes telangiectasia Subcutaneous nodules of calcinosis may be found, especially in the fingers and near the elbow joints The skeletal muscles may be weak and wasted

Visceral involvement is often discovered by special investigation in the early stages and as the disease progresses symptoms may be produced cough and dyspnœa from pulmonary lesions and dysphagia and constipation from alimentary lesions are common Heart failure may be caused by myocardial lesions or by the pulmonary fibrosis The spleen and lymph glands may be enlarged Albuminuria may be found but renal failure is rare

Special investigations—Radiography of the hands almost invariably shows re

sorption of the tufts of the terminal phalanges and there may be subcutaneous deposits of calcium Radiography of the chest may show reticulation due to pulmonary fibrosis or areas of pneumonia due to aspiration from the œsophagus there may be hypertrophy of the right side of the heart and the electrocardiogram may be abnormal Radiological investigation of the gastro intestinal tract is often abnormal in the œsophagus fibrous stricture dilatation absence of peristalsis and hiatus hernia have been described diminished peristalsis dilatation and diverticula have been seen in the small and large intestine

Course and Prognosis—Rarely there is rapid evolution of the disease with death in a few months More usually the disease is slowly progressive without remissions with increasing disability from Raynaud s phenomenon painful indolent fissures of the fingers limitation of movement of the fingers wrists elbows and shoulders increasing dyspnœa and perhaps dysphagia Death occurs in 5 to 10 years from inhalation broncho pneumonia heart failure or renal failure The disease may become arrested leaving the patient with residual deformities due to fibrosis

Diagnosis—In the early stages the aching and swelling of the fingers may suggest rheumatoid arthritis and Raynaud s phenomenon has to be distinguished from Raynaud s disease

Pulmonary involvement may be confused with bronchiectasis pigmentation with Addison s disease and œsophageal involvement with cardiospasm

Treatment—Local applications such as compound tincture of benzoin in lanoli may be necessary for the painful fissures of the fingers Raynaud s phenomenon should be treated in the same way as Raynaud s disease if it is severe cervical sympathectomy is justifiable although it has no influence on the course of the disease

Corticotrophin and cortisone may produce a temporary improvement in the œdematous stage but has no effect on the fibrotic lesions and it does not appear to have any effect on the ultimate prognosis

DERMATOMYOSITIS

Ætiology—The cause is unknown Males and females are equally affected the disease usually starts between the ages of 20 and 40 Some cases have been associated with carcinoma of the lung and other organs

Pathology—In the skeletal muscles there is parenchymal degeneration with an interstitial inflammatory reaction there is proliferation of nuclei of the muscle fibres and loss of the normal cross striations in the interstitial tissue there is a variable infiltration with lymphocytes histiocytes plasma cells and fibroblasts Later there is replacement fibrosis of the muscles Similar changes may be found in the myocardium In the dermis the collagen fibres may be swollen and homogeneous and there is a perivascular infiltration with lymphocytes and other cells

Clinical Picture—The onset is usually insidious but may be acute The early symptoms are muscular pain and weakness or subcutaneous œdema and erythema Occasionally Raynaud s phenomenon is the first symptom There may be generalised involvement of skeletal muscles from the start or the disease may begin in the limbs and spread to the trunk The neck shoulder and pelvic girdle muscles are most affected The muscles are painful tender and weak they feel indurated and later hard and fibrous

There is limitation of movement because of inability of the muscles to stretch The tendon jerks are diminished or absent Dysphagia dysphonia and dyspnœa are common from involvement of the pharynx, larynx intercostal muscles and diaphragm Facial weakness and diplopia may be found

Skin changes are rarely absent and may be persistent or transient The commonest change is a firm subcutaneous œdema which may be generalised but is usually confined to the face and limbs There may be a diffuse mottled purple

erythema, not necessarily coextensive with the œdema or the muscles involved, which is usually confined to the face and limbs Later there may be areas of pigmentation and atrophy of the skin, usually on the backs of the hands elbows knees or face Stomatitis with œdema, redness and crusted erosions, alopecia and subcutaneous calcinosis may be found Less common features are Raynaud s phenomenon, par æsthesiæ of the fingers and enlargement of the spleen, liver and lymph glands The temperature is usually normal or only slightly raised

Special investigations —Creatinuria is constantly found The radiograph of the chest may show enlargement of the heart and the electrocardiogram is occasionally abnormal Albuminuria is found in about half the cases

Course and Prognosis —The course is often indicated by the onset when the onset is acute the course is likely to be rapidly fatal, when the onset is insidious complete or partial remission is probable The muscular weakness progresses, steadily or with remissions in extent and degree About half the patients die in a few months to 5 years of broncho pneumonia or respiratory paralysis Occa ionally death is due to heart failure At any stage the disease may become arrested or regress leaving permanent incapacity from limitation of movement and residual changes in the skin of sclerodermatous thickening A few patients recover completely

Diagnosis —The skin lesions have to be distinguished from scleroderma dis seminated lupus erythematosus and poikiloderma atrophicans vasculare Oedema of the face with muscle pain may mimic trichiniasis If weakness is the outstanding feature polyneuritis and myasthenia gravis have to be excluded

Treatment —Dysphagia and respiratory paralysis are the chief cases of death, they may require treatment by gastric intubation pharyngeal suction and artificial respiration as in acute anterior poliomyelitis

Physiotherapy is necessary to prevent and correct deformities Corticotrophin or cortisone may arrest the progression of the disease and produce a complete remission

SCLEREDEMA ADULTORUM (BUSCHKE)

This is a condition in which œdema and induration develop in the skin and hypoderm usually after a period of fever It starts on the head and spreads over the neck and trunk Serous effusion into the pericardium, pleura and joints may occur but the disorder is self limited, clearing up after a few months to a year

Ætiology and Pathology —The cause is unknown

Histologically, there is swelling of the collagen with interstitial œdema and a slight perivascular inflammatory infiltrate

Treatment is symptomatic and supportive

SCLEREMA

Two types of this malady occur

In the *generalised form* (sclerema neonatorum) the skin all over the body is waxy, hard cold and pale or livid The temperature is subnormal Death may occur within the first week or two after birth but milder forms occur from which the infant may recover

Ætiology and Pathology —The olein content of the fat is diminished, giving the body fat a higher melting point with the result that solidification occurs at ordinary temperatures

Histologically there is crystallisation of the hypodermal fat, with an inflammatory infiltrate of foreign body giant cell type ending in fibrosis

In the *nodular form* (lipophagic granuloma) the histological features are the same but the process is localised and self limited the hard areas disappearing *in a few* months This form may affect adults and clinically resembles morphœa or paraffinoma (*q v*)

Diagnosis is usually made on histological grounds
Treatment —There is no effective treatment

ATROPHY OF THE SKIN

This occurs in the ageing skin but to a greater extent in areas exposed to light than in those not so exposed In its simplest form in covered areas there is thinning and loss of elasticity giving a yellowish wrinkled and tissue papery appearance and texture Histologically there is thinning of the epidermis with a flattened epidermo dermal junction The dermis is also thin and shows collagenous atrophy the hypo dermic fat is also less marked At sites exposed to light degeneration of the collagen and of the elastin are more marked both becoming basophilic and the latter being fragmented and forming irregular clumps

Senile elastosis (peasants skin) is a leathery thickening with marked furrowing occurring especially on the back of the neck (cutis rhomboidalis nuchæ) Histologic ally there is an apparent increase of elastic tissue with degenerative clumping swelling and fragmentation of its fibres

Glossy skin (atrophoderma neuriticum) occurs in conditions such as leprosy where there may be interference with the nerve supply to a part

Pressure atrophy occurs at sites of continuous pressure for example under the pads of trusses

Vulvar atrophy (senile atrophic vulvitis) may cause stenosis of the vaginal orifice (kraurosis vulvæ) The mucosa is dry shiny smooth and pale or there may be patchy telangiectasia and pigmentation Leucoplakia (mucosal hyperkeratosis) and even squamous carcinoma may be the final outcome Histologically the epidermis is thinned the collagen and elastin degenerated the blood vessels sclerosed and there may be lymphœdema of the upper dermis even going on to bulla formation

Macular atrophy (round and oval atrophic patches particularly on the trunk) may be an idiopathic condition or a manifestation of past secondary syphilis It may also occur in leprosy lupus erythematosus as a later stage of morphœa or as a part of the condition known as acrodermatitis chronica atrophicans The idiopathic form has two varieties one preceded by inflammation (Jadassohn) the other (Schwenınger Buzzi) having no earlier inflammatory stage Diagnosis is from von Recklinghausen s disease In both conditions there are hernia like orifices and grape like swellings in the skin but in macular atrophy the other features of von Recklinghausen s disease (*q v*) are absent

Macular and striate atrophy is seen in the condition sometimes called striæ cutis distensæ or striæ gravidarum This linear form of atrophy chiefly affects the breasts abdomen and thighs of pregnant women but is also seen in Cushing s syndrome and in some fat young people of either sex It is believed that in all cases an endo crine factor is responsible distension by itself not causing this condition as is clear from observation of fat persons The atrophic areas may be pink or purple when fresh skin coloured and more fibrotic when older

Atrophoderma reticulatum is a condition of pinhead sized atrophic ridges separ ated by narrow ridges of normal skin It occurs on the cheeks is of unknown cause and is untreatable except by cosmetic camouflage

Acrodermatitis chronica atrophicans is a disease which is rare in the British Isles and much more common on the Continent of Europe As the name implies it affects mainly the extremities where the skin is brownish red and swollen later becoming atrophic and wrinkled with subcutaneous veins clearly visible One or more limbs may be affected Usually fibrotic nodules and bands are present over the subcutaneous surface of the ulna or of the tibia Histologically there is hyperkeratosis thinning of the rest of the epidermis and œdema and degeneration of the collagen with a

erythema, not necessarily coextensive with the œdema or the muscles involved which is usually confined to the face and limbs Later there may be areas of pigmentation and atrophy of the skin, usually on the backs of the hands elbows, knees or face Stomatitis with œdema redness and crusted erosions, alopecia and subcutaneous calcinosis may be found Less common features are Raynaud s phenomenon, par æsthesiæ of the fingers and enlargement of the spleen liver and lymph glands The temperature is usually normal or only slightly raised

Special investigations—Creatinuria is constantly found The radiograph of the chest may show enlargement of the heart and the electrocardiogram is occasionally abnormal Albuminuria is found in about half the cases

Course and Prognosis—The course is often indicated by the onset when the onset is acute the course is likely to be rapidly fatal, when the onset is insidious complete or partial remission is probable The muscular weakness progresses steadily or with remissions, in extent and degree About half the patients die in a few months to 5 years of broncho pneumonia or respiratory paralysis Occasionally death is due to heart failure At any stage the disease may become arrested or regress leaving permanent incapacity from limitation of movement, and residual changes in the skin of sclerodermatous thickening A few patients recover completely

Diagnosis—The skin lesions have to be distinguished from scleroderma dis seminated lupus erythematosus and poikiloderma atrophicans vasculare Oedema of the face with muscle pain may mimic trichiniasis If weakness is the outstanding feature polyneuritis and myasthenia gravis have to be excluded

Treatment—Dysphagia and respiratory paralysis are the chief cases of death they may require treatment by gastric intubation, pharyngeal suction and artificial respiration as in acute anterior poliomyelitis

Physiotherapy is necessary to prevent and correct deformities Corticotrophin or cortisone may arrest the progression of the disease and produce a complete remission

SCLEREDEMA ADULTORUM (BUSCHKE)

This is a condition in which œdema and induration develop in the skin and hypoderm usually after a period of fever It starts on the head and spreads over the neck and trunk Serous effusion into the pericardium pleura and joints may occur but the disorder is self limited clearing up after a few months to a year

Ætiology and Pathology—The cause is unknown

Histologically, there is swelling of the collagen with interstitial œdema and a slight perivascular inflammatory infiltrate

Treatment is symptomatic and supportive

SCLEREMA

Two types of this malady occur

In the *generalised form* (sclerema neonatorum) the skin all over the body is waxy, hard cold and pale or livid The temperature is subnormal Death may occur within the first week or two after birth but milder forms occur from which the infant may recover

Ætiology and Pathology—The olein content of the fat is diminished giving the body fat a higher melting point with the result that solidification occurs at ordinary temperatures

Histologically there is crystallisation of the hypodermal fat with an inflammatory infiltrate of foreign body giant cell type ending in fibrosis

In the *nodular form* (lipophagic granuloma) the histological features are the same but the process is localised and self limited the hard areas disappearing in a few months *This form may affect adults and clinically resembles morphœa or paraffinoma* (*q v*)

are present and there is extensive atrophic and pigmented scarring over the elbows and knees Treatment is protective only

HYPERTROPHY OF THE SKIN

A corn (clavus) is a localised reactive hypertrophy the result of intermittent pressure and friction Histologically there is a dense hyperkeratosis with an acuminate downgrowth which presses the stratum mucosum down towards the dermis The stratum mucosum becomes thinned and atrophic Under the dermis there is often a bursa—a lymph space containing serous fluid Abacterial or bacterial inflammation may occur the latter sometimes with suppuration Corns most commonly occur on the upper surfaces of the toes particularly the small toes Sometimes they occur between the toes and owing to maceration are known as soft corns In this situation exostosis and fungous infection should be excluded as the cause Diagnosis is from warts by the fact that the latter either have a papillated surface or at least show a break in continuity of the epidermal lines of the skin Plantar warts may become buried under an hyperkeratotic cap Prevention is the ideal by suitable footwear Treatment consists of well fitting shoes and hose and paring of the excessive horny matter A salicylic acid plaster previously applied renders this procedure easier Recurrence is likely unless further pressure or friction is avoided

Callosities are diffuse thickenings of the horny layer without downgrowths such as occur with corns Callosities are due to excessive weight bearing as in obesity or from unnatural stresses as in pes planus They may also arise from roughened shoe linings and at innumerable sites in different occupations from intermittent friction and pressure (for example in gardeners boatmen housewives cobblers etc etc as occupational stigmata) Bursæ may form beneath the thickened firm inelastic skin which has a yellowish dirty appearance with a shelving edge and is painless Callosities are liable to undergo fissuring from which infection may result

Tylosis is a congenital hyperkeratosis of the palms and soles dominant in its inheritance The hard thickened skin cracks easily in the winter and becomes macerated and offensive in the summer The condition can be alleviated by 5 per cent salicylic acid ointment

Keratoderma climactericum affects the palms soles and heels and sometimes the knees of menopausal women usually obese There is much horny thickening at these sites and painful fissures tend to form around the heels Treatment is by œstrogens by mouth and salicylic acid ointment 2 to 5 per cent locally It is advisable to reduce the patient in weight by a stone or two in the course of a few months if possible

Keratoderma punctatum occurs in two forms one hereditary but occurring in early life the other apparently acquired and related to keratin stimulants operating around the sweat ducts On the palms (and sometimes on the soles) are discrete conical or rounded excresences of dense keratin with central puncta The condition is resistant to treatment but a 5 per cent salicylic acid ointment may help to soften the lesions

Arsenical keratosis (due to the ingestion of Fowler s solution) affects the palms with pinhead lesions although the soles may show larger excrescences Dirty grey keratoses and basal cell carcinomata may be present on the trunk and there may be raindrop depigmentation and pigmentation

Keratoderma blenorrhagica is an hyperkeratotic condition of the palms and soles and of the skin around and beneath the nails in which thick limpet like scaling and crusting occurs The condition is accompanied by urethritis polyarthritis and conjunctivitis The urethritis may be gonococcal or nonspecific Local treatment is with keratolytics

Porokeratosis of Mibelli is a congenital hyperkeratosis affecting in particular the

band like infiltrate of lymphocytes under the epidermis but separated from it by a thin band of relatively normal collagen There is also a perivascular infiltrate The hair papillæ and sebaceous glands are atrophic but the sweat glands survive under the thinned dermis The hypodermic fat is atrophic The cause of the malady is unknown It goes on from an early inflammatory and swollen stage to a later atrophic stage but it has no effect on length of life Diagnosis is from the main succulente of syringomyelia (by the absence of neurological signs), from erythromelalgia (by the absence of pain and warmth) Treatment is empirical Systemic penicillin has a reputation for bringing about an early remission

Poikiloderma —This is a condition of the skin in which telangiectasia pigmentation depigmentation and atrophy are intermingled It is an atrophic precancerous process

Ætiology and Pathology —Poikiloderma occurs after excessive solar or X irradiation It also occurs in an idiopathic form (poikiloderma vasculare atrophicans of Jacobi Lane) which may terminate in cutaneous reticulosis with tumour formation Poikilodermato myositis is an atrophic end stage of certain cases of dermatomyositis

The epidermis is atrophic and statically dilated blood vessels are present in the atrophic dermis

Course and Prognosis —All cases have to be watched for the development of keratoses or squamous carcinomata, or in the idiopathic form for reticulosis or mycosis fungoides

Diagnosis —The irradiation forms are usually easy to recognise from the history and situation The idiopathic form may occur with lichenoid papules on the trunk and with parapsoriasis like patches in addition to the poikiloderma

Treatment is by bland local applications for example hydrous ointment, and by appropriate action if malignancy occurs For cosmetic purposes the telangiectasia may be lessened by a touch with the galvano cautery or a suitable cover cream may be applied to mask the lesion

Poikiloderma atrophicans vasculare (Jacobi Lane) —This is a rare disorder of lichenoid papules with poikiloderma (pigmentation depigmentation telangiectasia and atrophy) The skin is dry and itchy The disorder is slowly progressive and may end in cutaneous reticulosis with tumour formation

Diagnosis is from radiodermatitis systematised lupus erythematosus and dermato myositis In radiodermatitis there is a history of irradiation in lupus erythematosus (*q v*) there are cytological and serological changes and in dermatomyositis there are muscle pains and creatinuria

Lichen sclerosus et atrophicus (see p 1279)

Pseudo xanthoma elasticum —This is a congenital abnormality consisting of a defect of the elastic tissue in the skin of the elastic membrane of the retina and of the elastic tissue of the arteries The eye changes cause angioid streaks due to defects in Bruch s membrane The skin lesions consist of yellow papules and plaques particularly around the neck tending to have a linear arrangement Histologically there is a patchy increase of elastic tissue with fragmentation and clumping in the deeper parts of the dermis This degenerate elastin stains with basophilic dyes The collagen is normal The histological picture resembles senile elastosis but the latter is more diffuse and the collagen is also degenerate On clinical grounds the conditions are not likely to be confused

Cutis hyperelastica (Ehlers Danlos syndrome) —This is a congenital abnormality in which there are hyperelasticity of the skin hyperflexibility of the joints scarring over the elbows and knees and soft polypi which result from injury and *hæmorrhage* into the over stretchable skin Histologically the elastic tissue is increased in amount and the fibres are coarse The collagen is atrophic and disrupted *The polypi* consist of collagen fibres with a foreign body giant cell reaction The patient shows double jointedness and is able to stretch the skin excessively Grape like swellings

ulcerate Histologically there are many histiocytes and an infiltrate in which eosinophil cells preponderate

Xanthelasma palpebrarum —In this condition there are flat or slightly raised deposi tions of cholesterol in the skin of the eyelids secondary to degenerative changes in the tissues The blood cholesterol may be normal or raised Sometimes there is diabetes but more often this is not so Under local anæsthesia the lesions can be destroyed with the cautery or the skin can be excised and left to heal without stitching

Juvenile xanthoma (nævo xantho endothelioma) presents as one or several yellow ish obtuse nodules on the limbs or on the neck and trunk of infants in the first year or two after birth The lesions regress spontaneously after a few years Histologically histiocytes containing fat (foam cells) are numerous with foreign body giant cells and there is proliferation of the vascular endothelium The blood cholesterol is normal

GRANULOMA ANNULARE

Granuloma annulare is a nodular non itchy eruption in the skin tending to form ringed lesions The cause is unknown Histologically there is a focal degeneration of the collagen giving it a ground glass appearance Around this area is an infiltrate of histiocytes lymphocytes and fibroblasts There is a deposition of mucin between the collagenous bundles The elastic tissue is degenerate A few epithelioid cells and foreign body giant cells may be present Children and young adults are mostly affected The mildest cases occur on the knuckles elbows or feet as skin coloured painless and non itchy nodules without epidermal changes Soon the nodule takes on a ringed shape or may extend in one direction and resolve in another so causing crescentic lesions A few patients have extensive and numerous lesions on the shoul ders buttocks and elsewhere as well as at the more usual sites

The lesions tend to continue indefinitely or may disappear without scarring at one site only to break out elsewhere They are however not known to be of any systemic importance and are consistent with good general health

Diagnosis is from periarteritis nodosa annular sarcoid tinea circinata and necro biosis lipoidica (*q v*) Nodules of the first named are painful The second is usually erythematous and not characteristically situated on the knuckles The third is an epidermal ringed eruption with scaling

Granuloma annulare tends to disappear after minor trauma has been applied Adhesive dressings carbon dioxide snow or slush applications or biopsy may all have this effect Treatment is unnecessary except on cosmetic grounds There is no effective systemic treatment

ERYTHEMA ELEVATUM DIUTINUM

Erythema elevatum diutinum occurs as the Bury type or as the Hutchinson type The Bury type is a firm raised dusky disc or ring of erythema It may represent the end stage of granuloma annulare The Hutchinson type consists of many firm nodules in a dusky background scattered widely over the trunk and limbs The lesions urticate on friction heat or excitement They persist indefinitely and end up as fibrous nodules The cause of the Bury type is unknown The Hutchinson type may arise from the persistent effects of an urticariogenic antigen leading to a refractory phase of the vessels so that damage occurs to the vessel walls Histologically in the Bury type there is a dense dermal mainly neutrophilic infiltrate especially around the vessels Sometimes eosinophils predominate (one form of eosinophilic granu loma) In the Hutchinson form a hyaline degeneration of the reticular fibrils around the vessels may be seen (toxic hyaline) Later fibrosis replaces the inflammatory process

Both conditions are chronic but the Hutchinson type is of more serious import because of the distressing itching and smarting

sweat duct ostia The lesions are grey or brown, warty elevations which spread peripherally, leaving a depressed, scaly, atrophic centre Treatment is by cautery destruction

Warty hard or epidermal nævi usually present as linear bands of itchy, brown warty cracked and bleeding skin The condition is unilateral, affecting the whole or part of a limb one side of the vulva, or the side of the neck or trunk (ichthyosis hystrix, nævus unius lateralis *linear nævus*) *Histologically there is* hyperkeratosis and papillomatosis but nævus cells are not present in the dermis Warty nævi are present at birth or develop at any time up to puberty and persist indefinitely Epithelioma may become superimposed Treatment is by protective dressings but if the lesion itches badly and tends to become excoriated and infected it is best excised and the area grafted

Lichenification is hypertrophy of the stratum mucosum (see Lichen Simplex)

Cutis laxa is an hypertrophy of the skin and subcutaneous tissue with lax attachment to the deeper structures with the result that the skin hangs in folds One variety is cutis verticis gyrata, a cerebriform folding of the scalp, sometimes congenital sometimes seen in acromegaly

DEGENERATIVE CONDITIONS

XANTHOMATOSES

Xanthoma tuberosum—This is a familial hypercholesteræmic xanthomatosis in which yellow nodules develop on the extensor surfaces of the elbows and knees the buttocks and elsewhere In the folds of the palms and soles there may be yellow streaks (xanthoma planum) Internal organs are also affected particularly mucous surfaces the tendons the endocardium and the intima of blood vessels Numerous xanthoma (foam) cells are seen in the dermis These are phagocytes containing lipoid material The cutaneous lesions are of no importance in themselves but the associated vascular lesions may cause death through coronary occlusion

The patient should be put on a diet with a small fat, vitamins A and D content By this means after several months the skin lesions may become smaller The aim of the treatment is to bring about a similar regression in the vascular lesions Lesions identical to those of xanthoma tuberosum also occur with *biliary cirrhosis* but in this condition the lesions are preceded by jaundice for months or years

Secondary xanthomatosis consists of yellowish red transitory, itchy papules, which consist of foam cells with an inflammatory reaction The condition is brought about by hypercholesteræmia and occurs in primary xanthomatosis diabetes mellitus (xanthoma diabeticorum) and biliary cirrhosis also in hypercholesteræmia sine xanthoma tuberosum Treatment is of the primary condition

Cholesterol histiocytoses are normocholesteræmic conditions reticuloses with secondary cholesterol depositions Letterer Siwe s disease is the infantile form in which petechiæ papules and pustules are observed and in which fever anæmia liver spleen and lymph node enlargement occur with multiple bony defects The condition is fatal before lipoid deposits develop in the skin

In the Hand Schuller Christian disease there may be diabetes insipidus exophthalmos dwarfism, enlargement of liver spleen and lymph nodes and bony defects The skin condition consists of yellowish macules and nodules with greasy overlying scales giving a resemblance to a mild infective dermatitis It tends to affect the scalp face and the flexures Petechiæ may also be present Histologically there are numerous histiocytes and some foam cells

Eosinophilic granuloma—This is a localised form of the same syndrome affecting chiefly the bones Sometimes the skin is affected with granulomata which tend to

GOUT

Gout —In this disorder of purine metabolism white nodules due to deposits of urates (tophi) are found in the cartilage of the ears and in the subcutaneous tissues around joints particularly the metacarpophalangeal joints of the great toes

MYXŒDEMA

Myxœdema —In generalised myxœdema the skin is dry pale and thickened In circumscribed (cutaneous) myxœdema which occasionally develops after operations on the thyroid or with thyroid adenomata firm raised dome shaped waxy skin coloured or yellowish nodules and plaques form mostly on the anterior aspects of the legs sometimes also on the face or arms Histologically the lesions contain a large amount of mucin Treatment is ineffective

EPIDERMAL TUMOURS

BASAL CELL PAPILLOMA (SENILE OR SEBORRHŒIC WART)

Basal cell papillomata are light to dark brown roughly papillated excrescences with non infiltrated bases and a greasy candle wax texture They occur with increasing frequency after the age of 40 and affect especially the scalp the face and the trunk They can easily be scraped off exposing a raw fleshy base

Ætiology and Pathology —Their cause is unknown They are believed by some to be infective by others to be a late nævoid condition

Histologically there are small epithelial cysts due to invagination of the epidermis There is also acanthosis with prolonged rete ridges The dermis shows little inflammatory reaction

Course and Prognosis —These lesions are benign but they may become secondarily infected

Treatment —For small superficial lesions brief (1 second) applications of carbon dioxide snow are effective Larger lesions are best dealt with by curettage and cautery under local anæsthesia

SQUAMOUS CELL PAPILLOMA (JUVENILE OR INFECTIVE WART VERRUCA)

Ætiology and Pathology —Warts are infective epidermal tumours caused by a virus They are auto inoculable and may appear in linear form in scratch marks They are commonest in childhood and young adults though elderly persons may be affected

Histologically there is focal acanthosis and gross hyperkeratosis with a variable degree of inflammatory infiltrate in the dermis The epidermo dermal junction is intact with no evidence of invasion of the dermis Mitoses may be numerous

Clinical Picture —Warts are described on a morphological basis as plane acuminate filiform digitate etc and from their situation as genital plantar etc On the scalp they tend to be digitate in the beard area filiform on the faces of children plane on the hands and knees grey brown circular excrescences (common warts verrucæ vulgaris) except around or under the nails where they may resemble hangnails or corns with considerable discomfort On the genitalia warts are usually acuminate (condylomata acuminata) and on the soles of the feet they are painful inverted embedded in hyperkeratosis and perhaps confluent in a mosaic pattern

Course and Prognosis —This is extremely variable Warts may disappear

Treatment is symptomatic and largely ineffective In the Bury form carbon dioxide snow is worth a trial In the Hutchinson form, antihistamine drugs may reduce the itching and urtication

NECROBIOSIS LIPOIDICA

Necrobiosis lipoidica is a condition in which lipoid deposition occurs in areas of degenerate or necrobiotic collagen Diabetes mellitus is often present or may subsequently develop Ill defined areas of poorly staining somewhat basophilic collagen are present in the dermis The collagen bundles are disorderly and disrupted In and around the area is an infiltrate of lymphocytes, histiocytes and fibroblasts A few epithelioid and foreign body giant cells may be seen and sometimes foam cells The blood vessels show fibrosis and endothelial proliferation, often with thromboses Stains for fat show much extracellular lipoid material

The lesions usually appear on one or both shins but are occasionally seen at the ankles on the feet or hands or elsewhere They consist of slightly depressed plaques of shiny atrophic, waxy yellow skin, with well defined margins and dilated venules showing clearly The centre may ulcerate On the hands the appearance differs the lesion resembling granuloma annulare

The malady often becomes inactive after a time but it never regresses Diagnosis is from other atrophic conditions and from granuloma annulare In the latter the histological changes are very similar but more focal and vascular changes are not visible Mucin deposits are found but no lipoid as in necrobiosis There is no effective treatment

AMYLOIDOSIS

Amyloidosis can affect the skin in three ways primary systemic amyloidosis, primary cutaneous amyloidosis (lichen amyloidosis) secondary systemic amyloidosis

Primary systemic amyloidosis affects the skin particularly of the face with non itchy waxy yellowish semi translucent nodules and plaques Petechiæ may be present In addition there is extensive involvement of voluntary and involuntary musculature, the cardiovascular system and the gastro intestinal and genito urinary tracts Macroglossia occurs There may be multiple myelomata and Bence Jones proteinuria Radiographic examination of the bones and sternal biposy are helpful in diagnosis

Amorphous deposits of amyloid are scattered throughout the dermis In secondary systemic amyloidosis the skin is very rarely affected In primary cutaneous amyloidosis the lesions usually occur on the legs as very itchy lichen planus like nodules—conical brownish or violaceous verrucose lesions which may coalesce to form large plaques Deposits of amyloid are present in the upper dermis There is no effective treatment

CALCINOSIS

Calcinosis cutis may be the result of hypercalcæmia due to hyperparathyroidism excessive vitamin D (calciferol) therapy chronic kidney disease or gross destruction of bone as in osteomyelitis or malignancy The skin is rarely affected most deposits occurring in the kidneys lungs or stomach Far commoner is normocalcæmic calcinosis cutis secondary to some degenerative process in the skin hypoderm muscles or tendons Scleroderma or dermatomyositis are often present but sometimes no cause can be found The depositions mostly take place in the fingers wrists elbows and feet and can be felt as hard masses bulging the skin often white and sometimes ulcerating Treatment is of the primary condition when this is possible

Clinical Picture—Pearly yellow pink or skin coloured umbilicated nodules occur singly or in groups They may occur anywhere on the skin and transference may take place from the breast of a mother to the face of her suckling or in the ano genital region during coitus Secondary infection may cause a lesion to become grossly enlarged ulcerated and purulent or necrotic

Diagnosis from warts is simple if inspection is made with a hand lens

Treatment—A phenolised probe or pointed orange stick is forced into each lesion or the tumours can be curetted off Antibiotics are ineffective as a rule but one or two successes have been claimed

EPIDERMAL CYSTS (WENS)

Milia are pinhead sized white cysts in the epidermis They are usually multiple and are found with acne or on apparently normal skin on the face they may also develop over some pathological condition such as epidermolysis bullosa or pemphigoid

Large epidermal cysts are often found on the scalp behind the lobes of the ears on the face scrotum and elsewhere A few of them are sebaceous cysts which vary in size from a pinhead to a walnut and show a dimple representing the follicular opening

Ætiology and Pathology—Epidermal cysts are possibly derived from the lanugo hair follicles and consist of a whorl of epithelial cells Sebaceous cysts are believed to be nævoid They may occur in large groups in steatocystoma multiplex The cysts are lined with squamous epithelium and contain horny and sebaceous material

Diagnosis is from dermoid cyst lipomata and cystic acne (*q v*)

Treatment—The cyst is incised and its odourless contents are expressed In epidermal cyst this is sufficient but in sebaceous cyst the offensive cheesy contents are first expressed and then the capsule is pulled out with artery forceps If secondary infection has occurred it is only possible to incise the cyst and removal of the capsule has to be deferred until inflammation has subsided

DERMOID CYST

These rare tumours occur in the mid line of the body or at the outer end of the brow They are skin coloured and not dimpled The cyst is lined with keratinising cells and may contain rudimentary sweat glands and pilosebaceous follicles as well as layers of keratin sebaceous material and sometimes hair cartilage or bone

Treatment is by removal if desired

IMPLANTATION CYST

These occur in the skin or more often in mucous surfaces following an injury which carries epidermal cells through a break in the surface

Treatment is by excision

BASAL CELL CARCINOMA (RODENT ULCER)

Ætiology and Pathology—The cause of these tumours is unknown They usually occur in the fifth sixth or seventh decades but occasionally appear in early adult life The majority arise in the area enclosed by two lines drawn from the tip of the ear to the eyebrows and from the lobe of the ear to the mouth but no area of the skin is immune except the palms and soles rodent ulcers may develop on the scalp the chest or abdomen or on the limbs Apparent precipitating causes include sunlight heat mechanical trauma and the ingestion of inorganic arsenic

Histologically there is a proliferation of basal cells without evidence of invasion

without treatment or they may spread They are amenable to suggestion in a proportion of cases They may recur even after the most careful curettage

Diagnosis may have to be made from one or other of keratosis corn callus, molluscum contagiosum, molluscum sebaceum squamous carcinoma papillary mole or nævus subungual exostosis acanthosis nigricans condyloma latum, verrucose lichen planus and lupus verrucosus (q v) Histological examination is sometimes necessary

Treatment —A waiting policy is sometimes justifiable because a proportion of warts disappear spontaneously On the scalp and beard area a combination of curettage and cautery is best Plane warts on the face or hands may be dealt with by daily applications of 1 per cent brilliant green in collodion salicylic acid fractional X ray exposures are sometimes used but simple suggestion may prove just as effective

On the hands if suggestion and local keratolytics and caustics fail recourse may be had to curettage and cautery under local anæsthesia or to carbon dioxide snow applications 30 to 90 seconds on each occasion depending on the size and situation of the lesions at intervals of 2 to 3 weeks Carbon dioxide snow is especially useful for paronychial and subungual warts because it causes less deformity than curettage and cautery

On the genitalia podophyllin 20 per cent in liquid paraffin is the treatment of choice The application is made on gauze to the penis or vulva It is applied at bedtime and removed on rising the affected area being cleaned with liquid paraffin A similar application is made the next night but after this at least a week should elapse before any further treatment of this sort is given Podophyllin causes a brisk inflammatory reaction after which all or most of the warts are shed A second course of treatment a week later may dispose of the remnants Sometimes this treatment fails to relieve extensive vulvar warts and then curettage and cautery under general næsthesia may be necessary

Plantar warts may occasionally disappear spontaneously but usually it is necessary to treat them either by caustics podophyllin 25 per cent formalin 10 per cent or by carbon dioxide snow applications 30 to 90 seconds at each treatment X ray treatment is contraindicated it succeeds in only about 60 per cent of cases a success rate equalled by many simpler measures and far exceeded by curettage and cautery Further, if X ray treatment fails the tissue is left to some degree devitalised repeated X ray treatment can cause sloughing of the deeper tissues with much suffering and deformity and perhaps necessitating grafting

Curettage and cautery offers something above 90 per cent prospect of success The injection of the local anæsthetic is a difficult part of the procedure For this purpo e the patient lies prone on the operating table, this provides flexion of the foot and relaxation of the plantar fascia and also directs a timid patient s attention away from the field of operation The injection is made slowly if possible through thin skin at the side of the foot After thorough curettage the horny collarette is trimmed away and the whole area is cauterised

MOLLUSCUM CONTAGIOSUM

A virus infection of the skin characterised by globular slightly umbilicated nodules

Ætiology and Pathology —The condition is acquired by direct contact, non venereal or venereal

Histologically there is a symmetrical proliferation of the epidermis in oval or pear shaped lobules with degeneration of the epidermal cells caused by large cytoplasmic inclusion bodies homogeneous and eosinophilic which push the nuclei aside (molluscum bodies) The granular layer is thickened and a mass of horny material forms the central area of the tumour

Clinical Picture —Pearly yellow pink or skin coloured umbilicated nodules occur singly or in groups They may occur anywhere on the skin and transference may take place from the breast of a mother to the face of her suckling or in the ano genital region during coitus Secondary infection may cause a lesion to become grossly enlarged ulcerated and purulent or necrotic

Diagnosis from warts is simple if inspection is made with a hand lens

Treatment —A phenolised probe or pointed orange stick is forced into each lesion or the tumours can be curetted off Antibiotics are ineffective as a rule but one or two successes have been claimed

EPIDERMAL CYSTS (WENS)

Milia are pinhead sized white cysts in the epidermis They are usually multiple and are found with acne or on apparently normal skin on the face they may also develop over some pathological condition such as epidermolysis bullosa or pemphigoid

Large epidermal cysts are often found on the scalp behind the lobes of the ears on the face scrotum and elsewhere A few of them are sebaceous cysts which vary in size from a pinhead to a walnut and show a dimple representing the follicular opening

Ætiology and Pathology —Epidermal cysts are possibly derived from the lanugo hair follicles and consist of a whorl of epithelial cells Sebaceous cysts are believed to be nævoid They may occur in large groups in steatocystoma multiplex The cysts are lined with squamous epithelium and contain horny and sebaceous material

Diagnosis is from dermoid cyst lipomata and cystic acne (*q v*)

Treatment —The cyst is incised and its odourless contents are expressed In epidermal cyst this is sufficient but in sebaceous cyst the offensive cheesy contents are first expressed and then the capsule is pulled out with artery forceps If secondary infection has occurred it is only possible to incise the cyst and removal of the capsule has to be deferred until inflammation has subsided

DERMOID CYST

These rare tumours occur in the mid line of the body or at the outer end of the brow They are skin coloured and not dimpled The cyst is lined with keratinising cells and may contain rudimentary sweat glands and pilosebaceous follicles as well as layers of keratin sebaceous material and sometimes hair cartilage or bone

Treatment is by removal if desired

IMPLANTATION CYST

These occur in the skin or more often in mucous surfaces following an injury which carries epidermal cells through a break in the surface

Treatment is by excision

BASAL CELL CARCINOMA (RODENT ULCER)

Ætiology and Pathology —The cause of these tumours is unknown They usually occur in the fifth sixth or seventh decades but occasionally appear in early adult life The majority arise in the area enclosed by two lines drawn from the tip of the ear to the eyebrows and from the lobe of the ear to the mouth but no area of the skin is immune except the palms and soles rodent ulcers may develop on the scalp the chest or abdomen or on the limbs Apparent precipitating causes include sunlight heat mechanical trauma and the ingestion of inorganic arsenic

Histologically there is a proliferation of basal cells without evidence of invasion

Globular clumps of darkly staining basal cells are seen The cells may remain undifferentiated or may show differentiation towards horny or glandular structure (keratotic adenoid and cystic rodent ulcers) The cellular mass expands horizontally and vertically If expansion is mostly horizontal (superficial rodent ulcer) the tendency to ulceration is less marked if it expands vertically the mass finally reaches a size in which the nutrition of its more centrally and superficially placed cells is inadequate and ulceration results

Clinical Picture —The appearance of rodent ulcers is extremely variable depending on the situation superficiality or depth and presence or absence of ulceration or infection Types include (1) the button like nodule (2) the pigmented nodule, (3) the rodent ulcer (4) the superficial type (5) the cicatricial type (6) the morphœa like scalp lesion (7) the cystic type Rodent ulcers may be multiple

The most common form is a pearly nodule which expands to form a button like tumour with small vessels coursing over its surface Sometimes the nodule is more globular and cherry like It may be skin coloured, grey or brown The rodent ulcer may bore deeply from the earliest stages (ulcus terebrans) or a nodule may only start to ulcerate after attaining a certain size, 1 cm in diameter or more In the first form there is a slightly raised rolled edge to the ulcerated area In the latter, the ulceration is at first a relatively inconspicuous feature in the centre of the nodule and gradually extends

The superficial basal cell carcinoma may be multiple It usually occurs on the trunk and often there is a history of prolonged medication with Fowler s solution It has a rolled edge so slightly elevated that it is not always easy to recognise it except with the aid of a hand lens The lesion resembles psoriasis, being a circumscribed irregularly red oval patch of abnormal scaling perhaps with some serous crusting in places The cicatricial basal cell carcinoma is also usually superficial but leaves a scarred and somewhat atrophic skin in the area behind its extending edge On the upper forehead and scalp basal cell carcinomata tend to develop horizontally and resemble morphœa (card like basal cell carcinoma) Rarely rodent ulcers a e clinically cystic This type tends to be dome shaped with a shelving edge and there may be considerable pigmentation

Course and Prognosis —The course varies according to the situation depth and amount of differentiation The superficial type may slowly extend parallel with the surface for many years The ulcus terebrans erodes early and deeply with the result that in a year or two important subcutaneous structures may be destroyed In these cases death may occur from hæmorrhage or secondary infection Metastases from basal cell carcinomata are very rare

Diagnosis —Rodent ulcers must be differentiated from granulomatous and reticulotic conditions from Bowen s disease and from psoriasis The long duration and hard pearly edge sometimes somewhat serpiginous usually makes the diagnosis easy Syphilitic ulcers are of short duration in relation to their size In some cases the diagnosis is not possible on clinical grounds and reliance has to be placed on biopsy and histological examination This also applies to the differentiation between recurrences of rodent ulcers and radiation necrosis or ulceration

Treatment —This consists of surgery with plastic repair when nece ary X irradiation or radium or in a few superficial examples destruction by carbon dioxide snow Surgery to be effective must include an area of apparently normal skin all round the lesion at least 0 75 cm wide This may be easy in some places impossible or too disfiguring in others Surgery is a necessity in dealing with recurrences where further X irradiation is thought to be inadvisable it may entail extensive plastic repair

X irradiation is best for lesions in situations which render excision difficult The total dosage used by radiotherapists varies A total of 3600 r, fractionated so as to give 720 r daily for 5 days, gives a better cosmetic result than 3600 r at one

treatment Some prefer a total dosage of 4500 r claiming that recurrences are less likely but it is probable that more recurrences are due to insufficient coverage of the apparently normal zone around the lesion than to insufficient dosage Basal cell carcinomata spread along the lymphatics beyond the visible edge and it is this clinic ally imperceptible spread that leads to recurrence unless a zone 0 75 cm to 1 cm wide is irradiated as well as the visible tumour

Radium is sometimes more useful than X rays and can be used as moulded surface applications or as needles or seeds of radon

Carbon dioxide snow is sometimes used for superficial rodent ulcers on the trunk applications of 90 seconds duration are made under firm pressure The resultant reaction has to be treated like a burn

SQUAMOUS CELL CARCINOMA

A tumour which is more rapidly growing than the basal cell carcinoma and which may give rise to metastases

Ætiology and Pathology —Squamous cell carcinomata are of varying grades of malignancy Some tend to form horn and are of low malignancy in others the cells remain undifferentiated and the lesions are more malign

Clinical Picture —The lesions are firm and nodular with shelving edges and rapidly ulcerate or form cauliflower like growths There is no rolled edge The sites most often affected include the face lower lip ear and the backs of the hands Squamous carcinomata are usually preceded by one or other of the precancerous conditions mentioned in the next section They rarely arise on apparently healthy skin usually the preceding pathological condition is brought about by excessive and prolonged solar irradiation by past X ray treatment or by some other physical irritant Glandular metastases occur early particularly from the ear lip or hand

Course and Prognosis —The lesion extends at first within the dermis and then invades the hypoderm At this stage spread by the lymphatics to the lymph nodes is more likely These lesions are as a result much more likely to be fatal than are basal cell carcinomata

Treatment is by excision or X irradiation On the lip and ear wedge excision offers the best prospects At other sites too surgery is preferable to X rays because the cells may be relatively radio insensitive Sometimes a combination of excision and irradiation is used Block dissection of the lymph nodes draining the area may be necessary Biopsy may be performed on skin sites if it is considered necessary but on the vermilion surface of the lip it is inadvisable Here V excision should be done and histological study made of the excised material

SECONDARY CARCINOMA OF THE SKIN

This occurs by lymphatic spread from a breast cancer or as cutaneous metastases usually from the breast (rarely from stomach uterus lungs prostate or ovary)

In the first form there is a hard red but pitting area of skin with a well marked border (carcinoma erysipelatoides cancer en cuirasse) It usually occurs in the axillæ or on the chest perhaps following a radical mastectomy

The metastatic form occurs as one or several firm white nodules in the skin the nature of which may be suspected or only discovered by biopsy

Treatment is symptomatic because the primary lesion may still be present or other inaccessible secondaries may exist

PRE MALIGNANT AND BORDER LINE CONDITIONS

Kerato acanthoma (molluscum sebaceum) is a benign neoplasm of the skin which though histologically resembling a squamous and horny carcinoma has a self limited

natural history ending in spontaneous resolution at about 3 months Its histological structure is that of a symmetrical and molluscoid squamous horny carcinoma.

Tar warts are possibly a variety of kerato acanthoma but are more uncertain in their course, some being shed while others go on to carcinoma Kerato-acanthoma sometimes arises on normal skin whereas squamous carcinomata arise at sites of keratoses and other epidermal abnormalities The lesion is button shaped with almost vertical edges whereas in squamous carcinoma the edge is shelving In the centre of the button is a horny plug Ulceration does not occur If nothing is done the nodule shrinks up and disappears, leaving an irregular crater with thickened lips of epidermis

Treatment —Thorough curettage of the lesion usually gives a better cosmetic result than X-ray treatment or waiting for spontaneous clearance If doubt exists as to the diagnosis the lesion should be treated as for squamous carcinoma either by wide excision or by adequate X-irradiation

BOWEN'S DISEASE

This precancerous condition may occur on the face, body or limbs

Pathology —There is an irregular acanthosis and large cells with dark nuclei and vacuolation of the cytoplasm are scattered through the epidermis They are similar to the cells seen in Paget s disease of the nipple

Clinical Picture —The lesions are usually itchy, pink and brown scaly or papular patches, sometimes slightly exudative with well marked but not rolled edges

Course and Prognosis —If untreated a termination in squamous carcinoma is likely after an interval of months or years

Diagnosis from superficial rodent ulcer is by the absence of a rolled edge from psoriasis by the absence of lesions elsewhere the chronicity of the lesion at one site the itching and the absence of typical psoriatic scales From mildly infected eczematous dermatitis the differential diagnosis may be impossible on clinical grounds alone and biopsy is then advisable

Treatment is by carbon dioxide snow, a firm application lasting 90 seconds This causes an inflammatory reaction sloughing of the affected area and replacement of the pathological skin by a smooth scar X ray treatment may also be used in doses equal to or greater than those used for skin cancers Sometimes excision is more suitable

PAGET S DISEASE

A pathological condition of the nipple and its ducts occurring with or soon followed by carcinoma of the nipple ducts

Pathology —There is parakeratosis with irregular acanthosis and clear 'Paget cells' scattered in the stratum mucosum

Clinical Picture —There is scaling and pinkness of the skin around one of the nipples, with slight palpable thickening The nipple may be in part or totally, destroyed in the process or it may be retracted It is clearly smaller than the other nipple Lymph nodes are not usually palpable in the axillæ and no abnormality can be felt in the breast.

Course and Prognosis —Carcinoma of the duct coexists with Paget s disease or soon follows it The malady if untreated, leads to metastatic carcinomatosis

Diagnosis is from eczema of the nipple This may be secondary to scabies, or in adolescents and young women it may be a manifestation of the asthma prurigo syndrome or of neurodermatitis In either of these conditions infiltration of the lesions is absent and the nipple is intact and equal in size to the other nipple Eczema of the breast may also develop from maceration by milk and the use of rubber dress protectors by lactating women

Treatment is by mastectomy Lymph node dissection is usually unnecessary X irradiation is contraindicated

QUEYRAT S ERYTHROPLASIA

This is a rare condition similar to Bowen s disease but affecting the glans penis *or the vulva*

Clinical Picture —There is a clear cut shiny pink slightly infiltrated and elevated patch

Diagnosis is from psoriasis and chemical balanitis In doubtful cases biopsy is indispensable

Treatment is by X irradiation

ACANTHOSIS NIGRICANS

This occurs in a juvenile benign form and in an adult malignant form

Ætiology and Pathology —The juvenile form is of unknown ætiology possibly nævoid The adult form is nearly always associated with a carcinoma usually of the stomach

The histology of both types is the same and consists of marked hyperkeratosis and papillomatosis with an irregular acanthosis and hyperpigmentation in the melano blasts and melanophores

Clinical Picture —The skin of the flexures is darkened thickened and lies in velvety folds In severe cases of the adult form the lips gums tongue and œsophagus may also be affected Clinical examination may reveal evidence of a new growth but sometimes the most careful search gives negative results yet at post mortem a neoplasm is discovered

Course and Prognosis —The juvenile form is benign but the adult form nearly always ends in death from the associated visceral neoplasm

Diagnosis is from warty nævi which are usually unilateral and linear and not confined to the flexures Darier s disease has a somewhat similar distribution but is usually more widespread the individual lesions are harder and the histology is distinctive

Treatment —Laparotomy is justifiable even if a visceral neoplasm cannot be located by clinical methods

KERATOSIS SENILIS VEL SOLARIS

This occurs mostly on the exposed surfaces of the skin except the form that may develop after inorganic arsenic medication which occurs more on the trunk than on the exposed parts

Ætiology and Pathology —Damage to the skin by excessive solar or X irradiation or by the ingestion of arsenic is the chief factor Age is of secondary importance, the lesions occurring in children with xeroderma pigmentosa in relatively young persons who have been much exposed to the tropical sun but rarely occurring even in extreme old age unless there has been considerable exposure to the sun throughout life

Histologically there is hyperkeratosis and parakeratosis Acanthosis precedes a frank prickle cell carcinomatous proliferation

Clinical Picture —Ill defined or clear cut dirty grey hard rough and scaly areas of skin are seen on the face or on the backs of the hands

Course and Prognosis —At any time keratoses may take on malignant proper ties on the other hand they may continue for years without this change occurring

Diagnosis *is from seborrhœic warts Keratoses are hard* rough and dirty grey

in colour, while seborrhœic warts are soft or firm, of candle wax texture and with a shiny brown surface which is often papillated

Treatment is by freezing with carbon dioxide snow for 15 to 30 seconds, provided there is no infiltration of the base Once the base has become infiltrated, the lesion should be treated as a squamous carcinoma (*q v*) with or without preliminary biopsy

CUTANEOUS HORN

This is a keratosis in which horn formation is carried out to excess

Clinical Picture —A horn grows either from an area of squamous papillomatous change or from an area of squamous carcinomatous change In the former the base is not infiltrated in the latter it is hard and elevated

Treatment depends on the changes taking place in the base If they are simply papillomatous curettage of the lesion through its base and cautery are usually sufficient If there is a suspected carcinomatous base the lesion should be widely excised or dealt with by radiotherapy with or without a preliminary biopsy

LEUCOPLAKIA

This is keratosis of a mucous surface and like keratosis on the skin it may remain innocent or develop into carcinoma (see Diseases of the Lips and Mouth)

NÆVOID AND ORGANOID EPIDERMAL TUMOURS

These are tumours either present at birth or first appearing later in life but running a benign course

NÆVUS SEBACEUS (JADASSOHN)

This is a yellow slightly raised firm nodule with a papillated surface usually occurring on the scalp or face and present at birth

Pathology shows mature sebaceous glands

Course and Prognosis —At or after puberty a basal cell carcinoma may develop on a nævus sebaceus Apart from this the lesion remains static through life except for any secondary infection that may occur from trauma by a comb or some other means

Treatment is by excision if desired Cautery or diathermy are unlikely to be effective For carcinomatous changes excision possibly with grafting or radiotherapy is necessary

SENILE SEBACEOUS *NÆVUS*

This is probably a delayed nævus Like the nævus sebaceus it consists of mature sebaceous glands It occurs on the forehead or face of persons of 50 or over as yellowish somewhat translucent nodules No treatment is necessary but the cautery can be used to destroy it

ADENOMA SEBACEUM (PRINGLE)

This is not an adenoma but a sebaceous nævus with hyperplasia of blood vessels and connective tissue The lesions occur on the part of the face near the nose as yellow brown or purplish nodules with telangiectasia The condition is associated with epilepsy mental deficiency *nodular sclerosis* of the brain and tumours of the kidneys heart and other organs (epiloia) The brain and retinal tumours are glio

mata those of the heart rhabdomyomata and those of the kidneys angiomata fibromata adenomata or mixed tumours No treatment is necessary for the skin condition but the nodules can be destroyed with the galvanocautery

FORDYCE CONDITION

This consists of ectopic sebaceous glands in the mucous surfaces of the lips or of the cheeks The lesions are yellow pinhead or larger soft nodules the histology of which is of a sebaceous glandular nature No treatment is necessary Reassurance may be necessary that the lesions are not luetic tuberculous cancerous or lichen planus The condition is so common as to be regarded as physiological

SYRINGOCYSTADENOMA PAPILLIFERUM

This occurs as a skin coloured or yellowish papilliferous lesion with crusting on the scalp It is an adenoma of apocrine ducts It may occur together with sebaceous nævus and like the latter may be complicated by basal cell carcinoma Treatment is preferably by excision Destruction by galvano cautery is likely to be followed by a recurrence

HYDRADENOMA PAPILLIFERUM

This occurs on the labia majora and perineum as a solitary skin coloured nodule of split pea size or smaller Malignancy does not develop The condition is an adenoma of apocrine glands

APOCRINE EPITHELIOMATA

These are of two varieties in syringoma differentiation of the cells is towards apocrine duct cells in cylindroma differentiation of the cells is towards apocrine gland cells

Syringomata occur mostly in women as multiple skin coloured or yellowish soft nodules of pinhead size and larger on and around the eyelids on the chest and abdomen and sometimes elsewhere No treatment is necessary but for cosmetic reasons they may be treated with carbon dioxide snow or the galvano cautery

Cylindromata (turban tumours) occur as rounded smooth elevations on the scalp and sometimes on the face and upper trunk beginning in young adults and slowly enlarging up to the size of grapes sometimes giving the scalp a cerebral appearance Treatment is ineffective because the extent of the lesions makes surgery impracticable and radiotherapy is of no use

TRICHO EPITHELIOMATA (EPITHELIOMA ADENOIDES CYSTICUM) (BROOKE S DISEASE)

These occur as multiple skin coloured nodules resembling basal cell carcinomata developing in early adult life on the scalp and face It is a familial disorder The tumours contain numerous horn cysts and rudimentary hair Some areas may closely resemble basal cell carcinoma and occasionally after many years these tumours take on the properties of rodent ulcers

Treatment —The tumours are usually too numerous for surgery and they are radio insensitive Active treatment is therefore best deferred unless malignancy develops in any one nodule when either radiotherapy or surgery is necessary

CALCIFYING EPITHELIOMA (MALHERBE)

This is a rare solitary movable, sharply demarcated often encapsulated tumour situated in the lower dermis Histologically there are basal cells adjoining pale "ghost cells with a foreign body giant cell reaction nearby Diagnosis is made histologically from a calcified sebaceous cyst, which has squamous cells adjoining the cyst cavity Treatment is by excision

CHONDRODERMATITIS NODULARIS CHRONICA HELICIS

This condition presents clinically as a painful nodule on the helix It is best considered here although it is uncertain whether it is inflammatory or neoplastic It usually occurs in men it may be bilateral and it interferes with sleep by causing discomfort when the head rests on the pillow

Pathology —There is diffuse inflammation in the corium It has been suggested that it is a form of glomus tumour

Treatment is by wedge excision including a portion of cartilage Anything less leads to recurrence

TUMOURS OF THE DERMIS

MOLES

A mole (pigmented fleshy, sometimes hairy nævus) is an elevated light or dark brown firm fleshy nodule occurring singly or scattered over the face A papillated form also occurs

Pathology —There are orderly circumscribed clusters of nævus cells in the dermis separated from the epidermo dermal junction and showing no mitotic activity Mixed dermal and epidermo dermal junctional nævi also occur in which the active junctional component is potentially malignant

Course and Prognosis —Moles tend to enlarge as age advances and they also get more hairy Folliculitis may develop and cause tenderness and swelling but malignant degeneration rarely, if ever occurs

Treatment is unnecessary except as a cosmetic matter The hairs may be removed permanently by diathermy or electrolysis and this is often sufficient Excision may be performed but destructive procedures of cautery carbon dioxide snow or diathermy are inadvisable they may result in ugly scarring and cause incomplete removal Operations on moles necessitate removal of the dermis in full depth

LENTIGO MALIGNA

This is a state of premalignant proliferation of lentigo (*q v*) in the plane parallel to the surface It is to malignant melanoma much as Bowen s disease is to squamous carcinoma The lesions appear in elderly persons as a very dark brown impalpable expansion of a lentigo There is no lymph node enlargement

Pathology —There are no nævus cells in the dermis but there is great irregularity and dropping off of the cells at the epidermodermal junction into the dermis The basal layer is markedly pigmented and there are many clear cells

Treatment is by wide excision A margin of 1 cm or less may be followed by recurrence in the scar

MALIGNANT MELANOMA

This the most malignant of all tumours arises from lentigines lentigo maligna or from mixed or junctional nævi It may also arise from the choroid

Pathology —There is extreme disorganisation of the epidermodermal junction with much mitotic activity in atypical nævus cells Beneath is a dense inflammatory infiltrate invaded by strands of the pigmented nævus cells Often the epidermis becomes permeated by tumour cells and disintegrates leading to the characteristic bleeding or ulceration of these lesions

Clinical Picture —Any mole or lentiginous macule should be regarded with great suspicion if it enlarges becomes darker bleeds scabs or becomes ulcerated or painful The classical malignant melanoma is a dark brown or bluish black soft easily bleeding nodule If it arises from a lentigo maligna there is a flat surrounding impalpable dark zone of a somewhat lighter tint than the melanoma itself Regional lymph nodes may be palpably enlarged or there may be extensive lymphadenopathy beyond the reach of the diagnostician s finger for example in the iliac chain Some melanomata are light brown and a few are skin coloured (amelanotic) and perhaps difficult to recognise even on histological grounds from anaplastic carcinoma

Course and Prognosis of melanomata is grave in the extreme Even if removed at the first recognition metastases are only too often found already to have occurred Once a melanoma has taken on malignant proliferation therefore the prognosis should be guarded there may be no recurrence after operation or metastases may declare themselves after a technically perfect operation Metastasis may take place in the lymph nodes in the liver or lungs or in the brain giving rise to symptoms of a cerebral tumour sometimes long after the primary lesion has been removed

Treatment —Without performing a biopsy a suspected melanoma should be very widely and deeply excised On no account should the lesion be manipulated by forceps in the process of removal Sometimes for example with Hutchinson s melanotic whitlow amputation is a better plan More drastic block dissections of the regional lymph nodes are sometimes carried out Melanomata are non responsive to X ray treatment but X rays are sometimes used before excision to check mitotic activity during the time of removal

BLUE NÆVUS (MONGOLIAN SPOT)

This is a button like firm slaty blue nodule usually found in the sacral region

Pathology —Deep in the dermis are spindle shaped cells containing melanin and lying with their long axes parallel to the surface The epidermis is normal but with the upper dermis it acts as a light filter and so gives the nævus its bluish tint

Course and Prognosis —The lesion is benign and static No treatment is necessary but excision can be carried out if the patient wishes it

KELOID

A keloid is a pink or white firm raised tumour often with claw like extensions beyond the limits of the original scar Histologically there is fibroblastic proliferation in the early stage and dense fibrosis in the later stages Keloids may form for no obvious reason or at sites of ingrowing hairs acne wounds tattoo marks vaccination scars or burns Predisposition both racial and personal is marked the coloured races being most affected and some white persons more than others

Acne keloidalis nuchæ is probably a keloid due to ingrowing hairs True acne keloids occur on the face and trunk

Treatment —Repeated fortnightly carbon dioxide snow applications 10 to 30 seconds on each occasion may flatten the lesions or excision followed by radiotherapy to the scar may prove effective Excision alone is usually most disappointing recur rence taking place

FIBROMA DURUM (SCLEROSING HÆMANGIOMA DERMATO FIBROMA, HISTIOCYTOMA, FIBROMA EN PASTILLE)

These deeply situated, firm globular tumours occur in the skin of the legs more than anywhere else *They may be single or multiple* *The colour* may be pink, light brown, bluish or skin coloured depending on the amount of vascularisation, lipoid or hæmosiderin deposition or fibrous tissue They are usually painless

Pathology —*The histological appearance* varies with the degree of maturity Early tumours contain a preponderance of histiocytes and endothelial cells, older tumours contain fibroblasts and fibrous tissue Infantile xanthomata the yellow *nodules known as nævo xantho endothelioma* are histiocytomata

Treatment —Histiocytomata do not recur after excision

FIBROMA MOLLE (FIBROMA COLLI OR SKIN TAGS)

Fibroma molle is a soft, fleshy, sometimes pedunculated tumour, often found *on the necks and axillæ of middle aged women* *The histology is that of normal* connective tissue It is possible that these lesion represent a forme fruste of von Recklinghausen s disease

Treatment—Destruction or removal by means of the galvano cautery gives excellent results

DERMATO FIBROSARCOMA PROTUBERANS

This is a locally recurrent form of fibroma One or several grouped nodules *skin coloured or purple form an irregular mass which may ulcerate* There is local invasion of tissue but metastasis is unusual except after many years True metastasising fibrosarcoma is very rare on the skin

***Treatment** —Local excision should include a wide area of apparently normal* skin if recurrence is to be avoided

MYXOMATOUS DEGENERATION CYSTS (SYNOVIAL CYSTS)

These occur mostly on the fingers near the distal interphalangeal joints They *are tense translucent and globular and contain mucinous fluid* The wall of the cyst is made of fibrous tissue

COLLOID MILIUM

This is a pinhead sized, translucent yellow nodulation usually of the forehead The slimy contents are degenerate collagen and the cysts are lined with collagen

NEUROFIBROMATOSIS (VON RECKLINGHAUSEN S DISEASE)

In this malady there are numerous soft skin coloured or brownish *purple tumours*, mostly pedunculated varying in size from pinhead size to masses the size of an orange *(molluscum fibrosum)* Yellowish brown macules of varying sizes and shapes (cafe au lait spots) are also present

Pathology —Wavy nerve sheath fibrils in loose strands and whorls are inter*spersed* with reticulum fibrils and collagen Mucoid degeneration may occur The café au lait spots show an increase of melanin pigment

Clinical Picture —The fully developed clinical picture is characteristic but *formes* frustes also occur in which the diagnosis may be more difficult In addition to the skin lesions there may be nodules on the peripheral nerves and in the central nervous system in the chest or abdomen and under the periosteum

Course and Prognosis —Malignant change is rare in the skin lesions but more common in the visceral ones

KAPOSI S IDIOPATHIC HÆMORRHAGIC SARCOMA

This condition is probably a benign angiomatosis and is not sarcomatous Histologically there are spindle cells and numerous dilated blood vessels with extravasations

Clinical Picture —Brown or purple nodules develop usually on the feet sometimes on the hands or on other parts of the skin Visceral lesions are common particularly in the lungs and abdominal organs and lymph nodes The skin lesions are not tender They first appear in early or middle adult life mostly in Jews slowly enlarge and then become static or regress They may ulcerate

Course and Prognosis —The course is usually benign though occasionally sarcomatosis has been reported as a terminal feature

Treatment —Radiotherapy may diminish the size of the lesions Apart from this dusting powders to the feet and measures directed to preventing or controlling ulceration are indicated Watch must be kept for symptoms of visceral involvement

OTHER SARCOMATA

Liposarcoma myxosarcoma osteosarcoma rarely occur in the skin

LEIOMYOMA

Leiomyoma may be a solitary tumour or it may occur in groups

Clinical Picture —The tumours are split pea sized smaller in the grouped form or larger in the solitary type They are yellowish brown and very tender to the touch particularly the grouped form The grouped leiomyomata arise from the arrectores pilorum muscles and the lesions may occur on the face trunk or limbs particularly the extensor surfaces Solitary leiomyomata may arise from involuntary muscle in the skin of the breasts scrotum or labia majora or from vascular musculature (angiomyomata)

Treatment —The only effective treatment is excision

LIPOMATA

These are soft freely movable often ill defined tumours in the subcutaneous tissue They may be single and massive for example in the neck or multiple The latter variety may be painful (Dercum s disease)

Treatment is by excision when necessary

HÆMANGIOMATA

NÆVUS FLAMMEUS (PORT WINE STAIN)

This is a hæmangioma of statically dilated vessels present at birth and often persisting through life although some small lesions on the eyelids and face may disappear after a few weeks of extra uterine life

An hæmangioma at the nucha is very common (Unna s nævus physiological nævus) Other sites commonly affected are the mid line of the forehead and one half of the face or even one half of the whole or part of the body and limbs In this case there may also be asymmetry the limbs of the affected side being smaller than those on the sound side (hemiatrophy) The vessels in nævus flammeus may be barely visible or obvious capillaries or large purple venules perhaps with nodular excrescences

Course and Prognosis —Nævus flammeus usually persists for life, except for the transient form on the face Some of the darker port wine stains may become more irregular and scaly as time progresses

Treatment —If there is a diffuse pinkness without blood vessels visible to the naked eye a trial of thorium X applications is justified 1500 e s u in spirit being painted on at fortnightly intervals for about 12 applications Photographic control is advisable and if after 12 treatments there is little or no improvement, it is not justifiable to continue with this procedure Elevated areas may be destroyed and flattened with the galvano cautery For the rest cosmetic coverage offers the best prospects particularly in women Some cosmetic firms provide a service in large cities whereby patients with blemishes can by individual trial be supplied with a cover preparation most suited to their complexions In men the problem is more difficult and the patient may prefer to leave his lesion uncovered Plastic surgery is rarely feasible

NÆVUS VASCULOSUS (STRAWBERRY MARK CAVERNO CAPILLARY NÆVUS)

This has a characteristic natural history It may be present at birth or it may appear within the first 2 weeks of extra uterine life as a *bright red, flat or slightly raised* pinhead sized nodule which steadily enlarges until about 8 or 9 months of age, when its growth stops and its gradual regression begins, the lesion finally dis appearing without trace or with slight scarring at about 5 years of age

Sometimes these hæmangiomata develop on a markedly raised area of venous tissue but the ultimate prognosis is equally good Histologically there is vascular proliferation in a fibrous or fatty stroma

Strawberry nævi may occur anywhere on the skin but rarely cause serious incon venience unless they involve the mouth or the anus an ear or a finger Large hæman giomata or those at sites exposed to trauma or a great deal of movement may become ulcerated and infected

Treatment —Simple capillary and caverno capillary hæmangiomata are best left to run their natural course which ends in resolution at about 5 years of age Periodic inspection and measurement or photography with reassurance of the mother are usually sufficient It is wise to inform the mother that a waiting policy will give the best results in the long run whereas any interference will cause some scarring and, if the lesion is on the scalp loss of hair Radiotherapy of a strawberry nævus near the nipple of a female infant is likely to be followed by nondevelopment of that breast and irradiation of a lesion near a joint may interfere with the growth of a limb Applications of carbon dioxide snow made in the first few months while the hæmangi oma is growing may be followed by a ring shaped recurrence around the scar

If there is ulceration infection should be controlled with a *suitable antibiotic* and the lesion subsequently dressed with tulle gras until the ulcer is scarred over If hæmorrhage occurs it can be controlled by a pressure pad

Rapidly growing hæmangiomata around the mouth may have to be treated, injections of hot water or sclerosing chemicals excision or radiotherapy can be used, *depending on what is considered most suitable*

STELLATE HÆMANGIOMATA

These small spider nævi appear on the face or hands in young children They may become much more numerous in pregnancy and in the presence of liver disorders There is a central venule with radiating capillaries

Treatment —The galvano cautery point is applied cold to the central vessel the current is switched on and the point withdrawn when the patient flinches

SENILE HÆMANGIOMATA (CAMPBELL DE MORGAN SPOTS)

These pinhead sized or larger red spots occur more and more after the age of 40 particularly on the trunk and face On the scrotum they often have a rough surface (angiokeratomata) They have no significance as regards the general health and need no treatment

FAMILIAL HÆMORRHAGIC TELANGIECTASIA (OSLER)

In this disorder numerous hæmangiomata and telangiectases occur on the skin and mucous membranes the latter may cause hæmorrhages from the nose mouth stomach kidneys vagina or rectum

Treatment —Individual lesions can be destroyed with the galvano cautery

ANGIOKERATOMA (MIBELLI)

These are warty angiomata which occur on the extremities of young subjects

Angiokeratoma corporis diffusum are similar lesions but with rather less wartiness on the trunk and external genitalia There may also be proliferation of Bowman s capsules in the renal glomeruli of the vascular musculature and of the heart muscle

GRANULOMA TELANGIECTATICUM (GRANULOMA PYOGENICUM)

This is a rapidly growing hæmangioma which soon becomes eroded and infected It presents as a pink shiny orange pip sized exuding and bleeding nodule Histo logically there is great proliferation of capillaries and of fibroblasts

Treatment is by galvano cautery destruction

GLOMUS TUMOUR (GLOMANGIOMA)

These very painful nodules are formed from the neurovascular glomus an arterio venous anastomosis They are usually single flat or raised lesions on the finger tip nail bed or occasionally elsewhere for example on the forearm

Treatment is by wide excision

LYMPHANGIOMA

Lymphangiomata may be circumscribed and superficial or widespread cavernous and deep In the former translucent superficial lemon coloured or red vesicles are present in a group at birth or soon after The surface of the vesicles may be slightly warty Histologically there are dilated lymph spaces

Treatment is unnecessary but excision is sometimes performed

In lymphangioma cavernosum there is also hypertrophy of the connective tissue *causing macrocheilia macroglossia or enlargement of part or the whole of a limb* In this form treatment other than drastic surgery is rarely possible

JUXTA ARTICULAR NODES

These are painless firm subcutaneous fibrous nodules occasionally found near the elbows or knees or other joints in tertiary syphilis Non syphilitic juxta articular nodes also occur as in acrodermatitis chronica atrophicans (Pick Herxheimer)

PARAFFINOMA

Paraffinoma is a nodular fibrotic subcutaneous thickening somewhat resembling morphœa but due to injection of paraffin or camphorated oil the former sometimes

having been used in an attempt to iron out creases and saggings in the ageing skin and the latter having been used as a vehicle for certain subcutaneous injections

Histologically there is a "Swiss cheese" appearance of cavitation indicating where the oily substance was contained and around these spaces is an inflammatory and foreign body giant cell reaction with fibrosis The presence of the oil within the spaces can be demonstrated in frozen sections

Diagnosis is from lipophagic granuloma and morphœa on histological grounds

Treatment is difficult and usually inadvisable Sometimes excision and grafting is justifiable

CUTANEOUS RETICULOSES

MALIGN RETICULOSES

These serious systemic infiltrative disorders may be ushered in by general pruritus furunculosis, nonspecific eruptions urticarial pruriginous and eczematised lesions parapsoriasis en plaque, poikiloderma purpura erythroderma or cutaneous or subcutaneous obtuse dome shaped plum coloured or skin coloured nodules which may ulcerate When large tomato tumours form the clinical description of "mycosis fungoides" is sometimes used It is at present not possible satisfactorily to classify these maladies

Pathology—Biopsy from the cutaneous nodule shows a polymorphic infiltrate in Hodgkin's disease and mycosis fungoides The Sternberg Reed giant cells are pathognomonic of Hodgkin s disease and in the infiltrate there are also neutrophils many eosinophils plasma cells, histiocytes fibroblasts and immature reticulum and stem cells

In mycosis fungoides the infiltrate is similarly polymorphic but Sternberg Reed cells are absent Small accumulations of lymphocytes and histiocytes are present in the epidermis (Pautrier micro abscesses)

Clinical Forms—Hodgkin s disease may present with pruritus *furunculosis* a nonspecific eruption or tumours or ulcers having the specific pathology of the disease Tumours on the face may give a leonine appearance

In lymphatic leukæmia erythroderma (l homme rouge) is the commonest form but this may be preceded by pruritus and nonspecific eczematoid *lesions by* parapsoriasis en plaque and poikiloderma or by itchy pink plaques resembling urticaria The leukæmia may develop late in the course of the disease Large *fungoid* tumours may form (mycosis fungoides) with or without leukæmia Infiltrative skin lesions have also been described in monocytic leukæmia and rarely in myeloid leukæmia

Course and Prognosis—These maladies are all fatal after *intervals* varying between a few months and several years Death is usually due to pulmonary complications marrow destruction or involvement of other organs

Diagnosis—Reticulosis must be considered a possibility *in all persistent* forms of generalised pruritus furunculosis nonspecific eruptions parapsoriasis en plaque poikiloderma erythroderma tumours and ulcers of the skin Often the diagnosis can only be established after a long period of observation and *after repeated* biopsies

Treatment—General pruritus of Hodgkin s disease may be relieved by X irradiation of the epigastric region Erythroderma may be subjectively relieved by corticotrophin Earlier more superficial plaque *like erythematous* infiltration may respond well to weekly paintings with thorium X 1500 e s u per ml for as many treatments as may be necessary The tumours are usually radio sensitive at first responding to two or *three exposures* of 250 r each at weekly intervals As the disease progresses the tumours tend to become more and more radio resistant

having been used in an attempt to iron out creases and saggings in the ageing skin and the latter having been used as a vehicle for certain subcutaneous injections

Histologically there is a "Swiss cheese' appearance of cavitation indicating where the oily substance was contained and around these spaces is an inflammatory and foreign body giant cell reaction with fibrosis The presence of the oil within the spaces can be demonstrated in frozen sections

Diagnosis is from lipophagic granuloma and morphœa on histological grounds.

Treatment is difficult and usually inadvisable Sometimes excision and grafting is justifiable

CUTANEOUS RETICULOSES

MALIGN RETICULOSES

These serious systemic infiltrative disorders may be ushered in by general pruritus furunculosis nonspecific eruptions urticarial pruriginous and eczematised lesions parapsoriasis en plaque poikiloderma purpura erythroderma or cutaneous or subcutaneous obtuse dome shaped plum coloured or skin coloured nodules which may ulcerate When large tomato tumours form the clinical description of mycosis fungoides is sometimes used It is at present not possible satisfactorily to classify these maladies

Pathology—Biopsy from the cutaneous nodule shows a polymorphic infiltrate in Hodgkin s disease and mycosis fungoides The Sternberg Reed giant cells are pathognomonic of Hodgkin s disease and in the infiltrate there are also neutrophils, many eosinophils plasma cells histiocytes fibroblasts and immature reticulum and stem cells

In mycosis fungoides the infiltrate is similarly polymorphic but Sternberg Reed cells are absent Small accumulations of lymphocytes and histiocytes are present in the epidermis (Pautrier micro abscesses)

Clinical Forms—Hodgkin s disease may present with pruritus furunculosis a nonspecific eruption or tumours or ulcers having the specific pathology of the disease Tumours on the face may give a leonine appearance

In lymphatic leukæmia erythroderma (l homme rouge) is the commonest form but this may be preceded by pruritus and nonspecific eczematoid lesions by parapsoriasis en plaque and poikiloderma or by itchy pink plaques resembling urticaria. The leukæmia may develop late in the course of the disease Large fungoid tumours may form (mycosis fungoides) with or without leukæmia Infiltrative skin lesions have also been described in monocytic leukæmia and rarely in myeloid leukæmia

Course and Prognosis—These maladies are all fatal after intervals varying between a few months and several years Death is usually due to pulmonary complications marrow destruction or involvement of other organs

Diagnosis—Reticulosis must be considered a possibility in all persistent forms of generalised pruritus furunculosis nonspecific eruptions parapsoriasis en plaque poikiloderma erythroderma tumours and ulcers of the skin Often the diagnosis can only be established after a long period of observation and after repeated biopsies

Treatment—General pruritus of Hodgkin s disease may be relieved by X irradiation of the epigastric region Erythroderma may be subjectively relieved by corticotrophin Earlier more superficial plaque like erythematous infiltration may respond well to weekly paintings with thorium X 1500 e s u per ml for as many treatments as may be necessary The tumours are usually radio-sensitive at first responding to two or three exposures of 250 r each at weekly intervals As the disease progresses the tumours tend to become more and more radio-resistant.

BENIGN RETICULOSES

FOLLICULAR LYMPHOCYTOMA (LYMPHADENOSIS BENIGNA CUTIS, SPIEGLER FENDT SARCOID)

This occurs as one or more dome shaped nodules on the scalp face, ears nose, breasts genitalia or elsewhere

Pathology—The nodules consist of nests of lymphocytes

Course and Prognosis—There is some doubt about the benignity of this condition It is believed that after years the condition may develop into a fatal reticulosis

Treatment—The lesions usually flatten and disappear after two or three X ray exposures of 250 r each at weekly intervals

MILIARY LYMPHOCYTOMA

This is a condition of pinhead sized translucent nodules in groups which arise on the malar region or forehead Each consists of a circumscribed nest of lympho cytes The condition is not a reticulosis but is apparently an unusual reaction to light

Treatment is ineffective Light screening creams should be prescribed if only to prevent worsening

DISEASES OF THE HAIR

CONGENITAL CONDITIONS OF THE HAIR

These include pili torti (spiral twisting of the hair) monilethrix (beaded hair, the shaft being constricted with absence of the medulla at regular intervals as a result of which the hair breaks off short) congenital ectodermal defects in which the scalp hair may be delicate and fine or woolly or absent (congenital alopecia) In albinism the hair is white

ACQUIRED CONDITIONS OF THE HAIR

CANITIES (WHITENESS OF THE HAIR)

This may be physiological from the age of about 40 years onwards It may also be pathological and premature in endocrine disorders including hyperthyroidism and Simmonds disease There may be partial or general whitening of the hair that regrows after alopecia areata or in the involvement of hairy areas by vitiligo The hair may also become white after severe emotional disturbance

Treatment is by suitable dyes which may be of the harmless type for example henna or potentially harmful for example paraphenylenediamine Before using the latter a patch test should be performed to determine the presence or absence of sensitivity to the chemical It should never be applied to a scalp on which any cuts, abrasions scabs or redness exist

NON CICATRICIAL ALOPECIA (BALDNESS)

This may be local or general all the hair may be lost from a given area or there may be sparseness of the hair on the site (alopecia diffusa)

Alopecia areata is a complete loss of hair from a circumscribed area of the scalp or the beard More extensive forms result in the loss of all the hair from the scalp (alopecia totalis) and in the worst cases the hair of the beard lashes and brows axillæ and pubis and even the glabrous hair may fall (alopecia universalis)

Ætiology and Pathology—The cause is unknown but emotional factors are

prominent in about two thirds of the cases The condition may represent an hysterical symbolisation Histologically there is an inflammatory infiltrate around the hair follicles which leads to atrophic changes of variable degree after the milder forms, regrowth of hair may occur but after the severer forms the loss may be permanent. In long standing alopecia, the inflammatory infiltrate is absent and the follicular atrophy more marked

Clinical Pictures —In simple alopecia areata, there are oval or circular completely bald shiny patches which by confluence may form polycyclic areas There is no sign of inflammation and an absence of scurf At the margin of recent and extending patches " exclamation mark (club shaped) hairs are visible These are short hairs with their ends of greater diameter than the portion level with the surface of the skin First attacks of the condition often occur in children and young adults Ophiasis is a variety of alopecia with serpentine lesions

Course and Prognosis —Recovery is usual from first attacks and localised lesions but becomes increasingly unlikely with each recurrence Sometimes one patch develops while another is regrowing The band like forms affecting the occipito temporal regions and alopecia totalis are of poor prognosis When regrowth occurs the new hair is at first fine and often white

Diagnosis —In children alopecia areata has to be differentiated from tinea capitis and from trichotillomania Tinea capitis presents as scaly patches with short broken hairs looking thicker than the adjoining healthy hairs and with frayed ends The inflammatory reaction may be insignificant or frankly folliculopustular Wood s light examination and microscopy makes the diagnosis clear The black dot ' ringworm due to *T violaceum* in which the hairs break off flush with the surface of the skin may resemble a regrowing alopecia Microscopy is necessary for the differentiation Trichotillomania an habitual tugging twisting and manipulation of the hair, is usually situated in the frontal or temporal regions the hair loss is only partial and a history of hair tugging will be obtained if the parent is asked this question

In adults alopecia areata has to be differentiated from various forms of cicatricial alopecia (*q v*)

Treatment is supportive A stimulating liniment may be rubbed in daily or a second degree erythema exposure to ultra violet irradiation given once a week Psychotherapy is seldom effective Foci of sepsis and eyestrain are no longer regarded as of ætiological significance

The term *alopecia diffusa* implies a diffuse thinning of the hair over part or the whole of the scalp

Androgenic alopecia is the commonest variety, occurring in most males from about the age of 40 onwards and in some as early as 20 years of age The hair becomes thinner and finer in the bifrontal and vertical regions but remains in its former texture and thickness on the rest of the scalp Genetic (racial and familial) influences are important in its ætiology also the fineness of the hair There is at present no means of checking its progress except by control of the coincident scurf or mildly infective folliculitis (*q v*) Massage may do more harm than good and ultra violet irradiation has no effect Œstrogens too in practical doses are ineffective

Women also are sometimes affected with this type of hair loss after the menopause and there may also be hirsutes of male distribution Occasionally alopecia of androgenic type occurs after pregnancy in these circumstances non destruction of androgens by the liver is suspected as the cause

In *myxœdema* the hair over the whole scalp is thinned fine dry limp and lustreless but may recover some of its former texture by suitable dosage with thyroid extract

In *nutritional deficiencies* particularly of vitamins A and C the phrynodermatous process may involve the scalp causing loss of hair and a finer texture of those that remain

Defluvium capillorum is a term used for conditions of temporary or permanent occasional or recurrent falling of the hair from causes known or unknown including acute infections, emotional stresses, exfoliative dermatitis toxic processes and nutritional deficiency states acting indirectly through endocrine and metabolic mechanisms

In *infective* (*seborrhœic*) *dermatitis* the hair loss of masculine distribution that is so often present is accentuated by the folliculitis

In *secondary syphilis* there may be an irregular but diffuse loss of hair, giving a moth-eaten " appearance to the scalp

X irradiation is often used to bring about epilation of patients suffering from ringworm of the scalp A single X ray exposure of 400 to 450 r causes shedding of the hair after 3 weeks with complete regrowth starting in another 3 weeks Further exposures or a single exposure of more than 450 r may cause permanent epilation, with the development after a few years of the picture of chronic radiodermatitis (atrophy telangiectasia pigmentation and depigmentation)

Certain toxic substances have a direct action on the hair papillæ One of these, thallous acetate was used some years ago to bring about temporary epilation but its use has been almost completely abandoned owing to the small margin between the therapeutic and the toxic dosage the latter causing albuminuria blindness, coma and even death The use of this substance is strongly to be deprecated

FRAGILITAS CRINIUM

Breaking of the hairs at various distances from the scalp must be differentiated from defluvium capillorum The hairs show frayed and split ends and sometimes frayed nodose swellings on their shafts (trichorrhexis nodosa) The cause is undue drying and degreasing of the hair which may follow the excessive use of shampoos Bleaching agents may also be responsible The treatment is preventive by avoidance of these substances in excess Once it has occurred it may be helpful to prescribe a lotion of salicylic acid 2 per cent. oil of rosemary 2 per cent castor oil 12½ per cent in industrial spirit, for use as a hair dressing

PILI INCARNATI

Ingrowing hairs resembling folliculitis barbæ of mild degree (*q v*)

CICATRICIAL ALOPECIA

Scarring baldness has a large number of causes including

- Physical traumata—cuts burns X rays radium
- Chemical traumata—caustics etc
- Exanthemata—variola varicella zoster
- Drug intoxications—lichenoid mepacrine eruption
- Fungous infections—kerion favus
- Granulomata—syphilis lupus sarcoidosis leprosy halogen eruptions
- Reticuloses—lymphocytomata or lymphoblastomata Hodgkin s disease
- New growths—rodent ulcers
- Nævoid conditions—nævus sebaceus hydrocystadenoma papilliferum (both present as bald areas with yellowish papillomatous outgrowths)
- Skin diseases—lupus erythematosus lichen plano pilaris morphœa folliculitis decalvans acne varioliformis pseudo pelade

A few of these may be described in some detail

Radiogenic alopecia presents as poikiloderma that is a polymorphic and patchy picture of atrophy telangiectasia depigmentation and hyperpigmentation It is occasionally seen in patients who have been treated by X rays for ringworm of the

scalp in childhood The condition is irreversible and after several years keratoses and squamous carcinoma may develop

Varicella variola and zoster may show macular bald areas at the sites previously occupied by the vesicles

The lichenoid gold or mepacrine dermatosis presents as one of its features a patchy folliculitis of the scalp, beard eyebrows and lashes which is followed by baldness either temporary or permanent The history of drug treatment and the lichenoid features elsewhere help to supply the correct diagnosis

Favus may present with scutuliform crusts with an offensive odour or as folliculitis decalvans (*q v*) Affected hairs fluoresce pale blue under Wood s light and spores and mycelium are visible within the hair shafts on microscopic examination

Syphilis in addition to the ' moth eaten alopecia at the secondary stage already mentioned, may in the tertiary stage cause cicatricial alopecia at the sites of gummata which in this situation often develop a heavy secondary infection

Leprosy may give rise to baldness in its nodular and in its maculo anæsthetic forms

Lupus vulgaris rarely involves the scalp and when it does the face is usually heavily affected as well with the characteristic 'apple jelly' nodulation

Reticuloses may cause obtuse skin or plum coloured dome shaped swellings with baldness on the scalp or occasionally more diffuse pink infiltrated nodulation

Rodent ulcer when it affects the vertex, differs considerably from the button like lesions seen on the face The scalp lesions are flat or even slightly depressed scleroderma like plaques perhaps with some crusting around the edges which also have a slight translucency and pearly appearance

Lupus erythemato us causes red bald patches with central atrophic carring and marginal infiltrated redness with follicular plugging and adherent scales

Lichen plano pilaris causes irregular areas of baldness and itchy acuminate violaceous follicular papules with shiny tops

Morphœa causes an oval or linear waxy shiny, bald area with a lilac halo

Folliculitis decalvans is a coccal folliculitis causing atrophy of the follicles and atrophic scarring with baldness Often the central area is bald apart from a few scattered hairs but shows no active inflammation towards the margin of the bald area are scaly follicular papules and sometimes a few pustules The condition can be controlled to some extent by appropriate antibiotics

Acne varioliformis leaves depressed hairless scars around the hair margin

Pseudo pelade presents a irregular and angular areas of scarred baldness with tufts of hair remaining amidst the bald patches The condition sometimes represents the end stage of lichen plano pilaris of the scalp

Ulerythema ophryogenes is a rare scarring folliculitis of the eyebrows of uncertain ætiology Sometimes it may be a manifestation of lupus erythematosus sometimes of coccal folliculitis profunda (sycosis)

Perifolliculitis capitis abscedens et suffodiens is a rare condition of fluctuant swellings on the scalp with sinuous tracks multiple sinuses and considerable loss of hair Culture may be sterile The condition is analogous to hydradenitis suppurativa and is most difficult to relieve It may be necessary to open up the tracks and allow them to heal by granulation

HYPERTRICHOSIS (HIRSUTES)

The localised form occurs as coarse hairs growing from a mole which is usually small and nodular but sometimes extensive and plaque like They rarely need treatment unless they occur on exposed surfaces when the patient may ask for something to be done on cosmetic grounds One of two courses should be adopted—either the hairs are destroyed individually by electrolysis or the whole mole is excised and

wound stitched or grafted Interfering traumatic procedures such as cautery or carbon dioxide snow freezing are to be deprecated the cosmetic results are poor and the depth of the lesions means that only excision can remove it all

Very rarely local hirsutes occurs over the sacrum without pigmentation, apparently as a vestigial tail

General hypertrichosis involves the areas of masculine coarse hairs the upper lip and beard area, the chest mid line of abdomen and subumbilical triangle and the extensor surfaces of the limbs Gross hypertrichosis is sometimes a source of embarrassment in the male in the female minor degrees may be equally distressing

Ætiology —The majority are genetic (racial and familial) in origin and no doubt related to a functional endocrine imbalance which is at present, incapable of adjustment. If the moon face obesity purple striæ hypertension and glycosuria are present (Cushing s syndrome) investigation should be made for pituitary or adrenal cortical neoplasia

The administration of adreno corticotrophic hormones may bring about acne and hirsutes

Acne vulgaris is often accompanied by hirsutes of moderate degree

Treatment —If there is no hypertension glycosuria moon face striæ or obesity and normal 17 ketosteroid excretion the condition can be regarded as genetic and is a functional endocrine disorder incapable (at present) of relief except by local epilatory methods

For coarse hairs electrolysis carried out by an expert gives the best results but in inexperienced hands noticeable pinpoint scarring may follow If the hirsutes is widespread and finer electrolysis entails many tedious treatments and it is better to use some simpler method of masking the condition Bleaching with peroxide of hydrogen (neutralised) followed by exposure to daylight is often valuable Shaving is often the ideal method and does not as is supposed by some lead to coarsening of the hair Unfortunately it carries with it a discouraging sense of performing a masculine act and many women refuse this suggestion for that reason although they are prepared illogically to use pumice the equivalent of pre historic man s razor Chemical depilatories are more useful in the axillæ than on the face where any inflammatory reaction they might cause would be more unfortunate

Epilation by wax has a small sphere of utility for localised patches as a temporary measure Plucking too is commonly performed for this purpose but, if persisted in may end in some traumatic epidermal proliferation of the ostia of the follicles

X rays should never be used for cosmetic epilation of women s faces breasts or limbs because of the likelihood of chronic radiodermatitis developing and of subsequent keratoses and epitheliomata

DISEASES OF THE NAILS

The nails may be affected in various ways by local or general conditions congenital or acquired

PARONYCHIA

Paronychia or inflammation of the nail fold is due to micro organisms gaining entry through a break in the cuticular barrier and it may be acute or chronic

The *acute* form (paronychial whitlow) due to coccal infection presents as a red tender, cushion like swelling on one or both sides of the nail fold Yellowish discoloration due to pus formation is soon apparent A painless epidermal variety may be the unsuspected source of various staphylococcal infections of the skin

Treatment is by systemic penicillin in the earliest stage or by avulsion of the nail and a paronychial flap at the later stage The epidermal variety is easily dealt with by removal of the overlying epidermis and cleansing with 1 per cent cetrimide

If a paronychial whitlow persists neither resolving nor suppurating, consideration should be given to the possibility of its being an example of *Hutchinson's melanotic whitlow* (onychia maligna), a highly malignant condition masquerading as an infection and necessitating amputation (see Melanoma)

Chronic paronychia like the acute form is due to destruction of the protective cuticle on the nail plate This happens following the use of powerful detergents strong alkalis and soaps constant exposure to water, the use of cuticle removers and clumsy manicure Through the gap thus made pass detergents soaps alkalis and water which cause a chemical paronychia with alkalinity of the fold this predisposes to infection by organisms normally present on the skin such as monilia and *Staphylococcus saprophyticus*

The condition presents as persistent reddened cushion like swellings around the nail fold with a space between the fold and the nail into which a probe can be passed for a few millimetres There may be occasional exacerbations with a slight discharge of thin pus The nail plate is usually deformed (onychia) by irregular transverse ridging and grooving, with some discolouration Sometimes a nail becomes detached from its bed

Course and Prognosis —Untreated, the condition tends to persist indefinitely

Treatment —Wet work and the use of detergents and alkalis must be reduced to a minimum Rubber gloves if used should be worn for not more than 10 minutes at a time A water repellent barrier cream may be applied around the folds immediately before doing any essential wet work

Active treatment consists of the application of pigmentum magentæ to the nail fold twice a day by means of a camel hair brush This may succeed in the milder cases but in more severe ones a course of X irradiation (150 r fortnightly up to a total of 600 r) is often most effective

The patient must continue to take precautions against damage to the cuticle after the condition has healed

Tuberculous paronychia is very rare Its treatment is the same as that of cutaneous tuberculosis elsewhere

INGROWING TOE NAIL (UNGUIS INCARNATUS)

This nearly always affects the great toe and is due to a faulty technique of cutting the nail whereby a lateral sharp spur is left which cuts into the flesh tight socks and shoes also play a part The condition presents as a painful swollen area to one side of the toe near the free edge of the nail A purulent infection is common or a granulomatous condition

Treatment —In the early stages corrective chiropody may be sufficient but once a purulent or granulomatous condition has developed it is necessary to remove half the nail and to excise a wedge of tissue at the site of ingrowth to enable the nail to grow without cutting into the flesh

Hangnails are skin tags alongside the nail the result of faulty manicuring a tic or chapping The tag as it tears becomes of increasing depth The diagnosis is from paronychial warts (*q v*) The treatment is to cut off the tag and to apply an antiseptic and a collodion dressing

Subungual hyperkeratosis is usually due to psoriasis dermatitis or some other skin disorder Tinea must be excluded by microscopic examination

Subungual exostosis presents as a painful swelling beneath the nail, with some

hyperkeratosis The condition is differentiated from a subungual wart by X ray examination and the treatment is surgical

Subungual warts (see Warts)

DISORDERS OF THE NAIL PLATE

Affections of the nail plate, secondary to disease of the matrix are many and various The nails may undergo atrophy or complete destruction (acquired anonychia) or hypertrophy, the latter either as a simple thickening following trauma (onychauxis) or as ram s horn like masses (onychogryphosis or ' claw nails) For convenience the thickened nails may have to be removed but the new nails will be just as thick Excision of the nail beds is sometimes advisable but it is a delicate surgical procedure to remove all the bed proximally and laterally without opening the distal interphalangeal joints

Congenital abnormalities include absence of the nails (anonychia) rudimentary nails ectopic nails (onychoheterotopia) spoon shaped nails (koilonychia) extreme thickening (pachyonychia congenita)

Tics affecting the nail and its surrounds include nail biting (onychophagia) and picking (onychotillomania) one form of hangnail and knuckle chewing

Dystrophy (dullness and roughening) of the nails may be due to ringworm psoriasis dermatitis lichen planus syphilis tuberculosis leprosy or unknown causes Ringworm should always be suspected when one or a few nails are discoloured, irregular friable or honeycombed Microscopy repeatedly if necessary enables the diagnosis to be confirmed

Psoriasis of the nails usually occurs with psoriasis elsewhere so that the diagnosis is simple but it may affect the nails alone It presents as thimble pitting of the nails there being anything from a single pit to uniform involvement of all the nails In its more severe forms it causes yellow opaque brittle thickening of the nails usually distally or laterally sometimes over the whole plate The nails may be raised and shed by psoriasis of the nail bed

Dermatitis around and in the nail folds leads to pitting and transverse or longitudinal grooving of the nails

When dystrophy of the nails is not explicable as of fungous psoriatic or dermatitic origin the Wassermann reaction should be tested and examination directed especially to evidence of syphilis or of lichen planus elsewhere Median canaliform dystrophy is a permanent thickened ridge running along the centre of the nail and due to previous chemical or physical trauma to the part of the matrix supplying this portion of nail

Splitting of the nail tips into lamellæ (onychoschizia) is usually caused by powerful detergents or alkalis, occasionally nail manicure preparations and varnish removers are responsible

Transverse groovings and ridgings of the nails are spoken of as Beau s lines They may arise *in one or more nails from dermatitis psoriasis and other skin conditions* or they may indicate some recent illness for example pneumonia which has led to a temporary impairment of the nutrition of the nail They take about 6 months to grow out and from their situation on the nail the date of previous ill health can be roughly estimated

Longitudinal grooving and ridging of the nails is very common and of no significance in minor degrees but when severe and accompanied by *splitting of the nails* it is dignified by the name of onychorrhexis and attention should be paid to the avoidance of degreasing and dehydrating substances

White spots on the nails (canities unguium or leuconychia) are of no diagnostic significance or import except that they indicate areas of imperfect cornification possibly the result of injury

Longitudinal bands of variation in colour either lighter or darker may result from local pigmentary changes in the matrix

Koilonychia may be congenital and of no serious import When acquired it often indicates a chronic malnutrition of the matrices *from iron and vitamin B deficiency* A general cause cannot always be found and local ischæmic proces es are ometimes *responsible* Damage to one or more fingers may cause a somewhat similar deformity except that the nails are not thin as they *are in nutritional* koilonychia

Clubbing of the fingers includes an increased curvature of the nails both in the longitudinal and transverse axes and an increased springiness of the nails on their beds *It is* associated with suppurative lung conditions and cyanotic congenital heart disease etc There is often also hypertrophy of the distal phalanx (hypertrophic pulmonary osteoarthropathy)

Detachment of the nail from its bed may start proximally (onychoptosis) from hæmatoma or paronychia or distally (onycholysis) as in psoriasis Onychomadesis is a term applied to shedding of all the nails (sometimes recurrently) starting proximally The causes of this phenomenon include vasospastic states skin diseases beneath the nails for example exfoliative dermatitis or psoriasis chemical contact injury syphilis diabetes or scarlet fever in its peeling stage

Usure des ongles is a term applied to wearing away of the free border of one or more nails as the result of occupational friction or even merely rubbing with the finger tips

CONDITIONS OF THE NAIL BED

Conditions of the nail bed observed through the plate include the splinter *hæmorrhages*' of lupus erythematosus, purpura hæmatomata cyanosis stains of various chemicals and racial pigmentation

DISEASES OF THE LIPS AND MOUTH

The lips and mouth are affected in many skin diseases which have been described elsewhere It remains to describe a few other conditions affecting the lips and mouth

CHEILITIS

Commissural cheilitis (angular stomatitis) causes redness, slight crusting and fissuring It may be a form of infective (flexural) dermatitis or a manifestation of deficiency of iron and vitamin B or due to falling in of the angles of the mouth and a resultant extension of the moist surface, arising from lack of teeth or from dentures which are too narrow and shallow or it may be due to salivation resulting from hypersensitivity to vulcanite or acrylic denture material to tooth paste mouth wash or fruit juices It should be remembered that frambœsiform syphilides may develop in this situation or at the cleft of the chin

Cheilitis exfoliativa is a peeling of the vermilion surface of the lips u ually due to contact with a sensitiser In severe forms there is œdema, vesiculation and cru ting, perhaps going on to fissuring Eosin in lipstick is the commonest cause this may act either by causing a contact eczematous reaction or by causing sensitisation to ultra violet rays In the former both lips may be affected In the latter the lower lip alone suffers Rarer causes include nail varnish tooth paste mouth washes fruit juices essential oils nicotine mentholated cigarettes chemicals handled at work and a lip sucking and chewing habit

Cheilitis glandularis is a rare condition of unknown cause The mucous glands are enlarged and there is a glairy exudate with some crusting Treatment is by cautery destruction of the swellings

Macrocheilia may be congenital or acquired The latter is usually due to lymphatic obstruction secondary to streptococcal cellulitis the infection gaining entry through

a fissure but syphilis and tuberculosis are also sometimes responsible for this elephantiatic condition

Conditions of the lips dealt with elsewhere include lupus erythematosus lichen planus psoriasis keratoses leucoplakia urticaria erythema multiforme, granuloma pyogenicum syphilis tuberculosis recurrent herpes and tumours Mucous (retention) cysts occur on the mucosal aspect

STOMATITIS

Inflammation of the mouth may cause diffuse redness erosions blisters submucosal hæmorrhages or ulcers *The tongue may exfoliate In more chronic forms redness* is inconspicuous and there is leucoplakia

Ætiology —Lesions appear in the mouth in infections with syphilis tuberculosis streptococci monilia Vincent s angina herpes simplex zoster varicella variola etc. Lesions also appear in intoxications by many drugs (*q v*) and heavy metals Nutritional deficiencies (scurvy pellagra) cause hæmorrhage and inflammation Blood disorders such as leukæmia agranulocytosis pernicious anæmia hæmophilia metabolic disorders such as diabetes mellitus and uræmia may all cause lesions in the mouth Finally certain idiopathic skin diseases may be responsible particularly lichen planus lupus erythematosus erythema multiforme pemphigus Behcet s syndrome Lipschütz disease and rare maladies such as epidermolysis bullosa Darier s disease and acanthosis nigricans

Syphilis —Primary lesions may occur on the lip tongue palate or tonsil and mucous patches and snail track ulcers may appear anywhere in the mouth Gummata may develop in the palate or tongue or there may be a syphilitic glossitis with irregular leucoplakia

Tuberculosis (see page 1241)

Streptococcal stomatitis may complicate tonsillitis There is a patchy or generalised cherry red and swollen condition of the gums

Monilial stomatitis (thrush) produces soft white rapidly spreading raised patches This malady may develop in infants or in adults who are taking antibiotics or using antibiotic mouth washes

Vincent s angina due to symbiosis between a spirochæte and fusiform bacillus causes grey patches in a red raw bleeding surface it particularly affects the gingivo-buccal margin or gingival sulci Gangrenous stomatitis (cancrum oris) is a very rare form of Vincent s infection in extremely debilitated children

Herpetic stomatitis first affects infants 2 to 3 years old This primary infection may be followed by a delicately balanced host virus relationship with recurrences of aphthous stomatitis when debilitated There are painful swollen erosions (aphthæ) on the cheeks gums or tongue

Zoster (see p 1247)

Varicella (see p 1248)

Variola (see p 160)

Stomatitis medicamentosa —Iodides may cause hæmorrhages or bullæ many other drugs may cause bullæ erosions ulcers and lesions resembling lichen planus or erythema multiforme (see Drug Eruptions)

Stomatitis due to heavy metals —Mercury in sufficient dosage causes salivation with gross swelling of the gums and tongue often accompanied by nephritis Lead causes a blue black discolouration of the gums opposite areas of marginal gingivitis (pyorrhœa) There may also be ulceration Silver causes a blue grey pigmentation or an increase of melanin pigmentation Bismuth may cause a similar discolouration and gold may cause stomatitis and pigmentation These metallic pigmentations have to be differentiated from that of Addison s disease and racial pigmentation which may occasionally be seen on the gums of white persons with some coloured ancestry as well as in the mouths of coloured people

Koilonychia may be congenital and of no serious import When acquired it often indicates a chronic malnutrition of the matrices from iron and vitamin B deficiency A general cause cannot always be found and local ischæmic processes are sometimes responsible Damage to one or more fingers may cause a somewhat similar deformity except that the nails are not thin as they are in nutritional koilonychia

Clubbing of the fingers includes an increased curvature of the nails both in the longitudinal and transverse axes and an increased springiness of the nails on their beds It is associated with suppurative lung conditions and cyanotic congenital heart disease etc There is often also *hypertrophy of the distal phalanx (hypertrophic* pulmonary osteoarthropathy)

Detachment of the nail from its bed may start proximally (onychoptosis) from hæmatoma or paronychia or distally (onycholysis) as in psoriasis Onychomadesis is a term applied to shedding of all the nails (sometimes recurrently) starting proximally The causes of this phenomenon include vasospastic states skin diseases *beneath the nails for example exfoliative dermatitis or psoriasis chemical contact* injury syphilis diabetes or scarlet fever in its peeling stage

Usure des ongles is a term applied to wearing away of the free border of one or more nails as the result of occupational friction or even merely rubbing with the finger tips

CONDITIONS OF THE NAIL BED

Conditions of the nail bed observed through the plate include the splinter hæmorrhages of lupus erythematosus purpura, hæmatomata cyanosis stains of various chemicals and racial pigmentation

DISEASES OF THE LIPS AND MOUTH

The lips and mouth are affected in many skin diseases which have been described elsewhere It remains to describe a few other conditions affecting the lips and mouth

CHEILITIS

Commissural cheilitis (angular stomatitis) causes redness slight crusting and fissuring It may be a form of infective (flexural) dermatitis or a manifestation of deficiency of iron and vitamin B or due to falling in of the angles of the mouth and a resultant extension of the moist surface arising from lack of teeth or from dentures which are too narrow and shallow or it may be due to salivation resulting from hypersensitivity to vulcanite or acrylic *denture material to tooth paste mouth wash* or fruit juices It should be remembered that frambœsiform syphilides may develop in this situation or at the cleft of the chin

Cheilitis exfoliativa is a peeling of the vermilion surface of the lips usually due to contact with a sensitiser In severe forms there is œdema vesiculation and crusting perhaps going on to fissuring Eosin in lipstick is the commonest cause, this may act either by causing a contact *eczematous reaction or by causing* sensitisation to ultra violet rays In the former both lips may be affected In the latter the lower lip alone suffers Rarer causes include nail varnish tooth paste mouth washes fruit juices essential oils nicotine mentholated cigarettes chemicals handled at work and a lip sucking and chewing habit

Cheilitis glandularis is a rare condition of unknown cause The mucous glands are enlarged *and there is a glairy exudate,* with some crusting Treatment is by cautery destruction of the swellings

Macrocheilia may be congenital or acquired The latter is usually due to lymphatic obstruction secondary to streptococcal cellulitis the infection gaining entry through

GLOSSITIS

Ætiological factors in this condition are alcohol smoking condiments and gastro intestinal and metabolic disorders (Plummer Vinson syndrome sprue pellagra, pernicious anæmia diabetes mellitus) Electrogalvanism from metals of different electro-potentials in dental prostheses can cause a metallic or salty taste salivation tingling shocks eroded gums or tarnished teeth

Moeller s glossitis (glossodynia exfoliata) is rare It chiefly affects women causing severe burning pain which makes feeding difficult There are red patches of denuded filiform papillæ and white leucoplakic nodules

Glossitis rhomboidea mediana is a lozenge shaped elevation in the mid line about the middle third of the tongue well defined anteriorly but fading posteriorly into the circumvallate papillæ It is due to the persistence of the tuberculum impar and is of no serious significance but is sometimes discovered accidentally by the patient who may think it is cancerous

Glossodynia —This may be symptomatic of irritation from heat alcohol or trauma of avitaminosis pernicious anæmia leukæmia drug intolerance (especially phenol phthalein) electrogalvanism xerostoma or cancerphobia It may also occur from changes in the temporo mandibular joints, usually due to lack of teeth resulting in abnormal stresses on these joints

Lingua geographica is often accompanied by soreness In this idiopathic condition there is a wandering superficial exfoliation which slowly changes its distribution day by day producing reddened denuded areas It is benign and patients fears of cancer can be allayed with confidence Treatment is palliative with normal saline mouth washes or, better still by ignoring it It tends to persist indefinitely

Lingua plicata (scrotal tongue) is a congenital malformation of deep sulci running in various directions Its significance is that it may lead to accumulations of food debris in these folds Careful hygiene is advisable perhaps using a wool tipped probe to clean out the sulci

Lingua nigra has two forms The black hairy tongue is an hypertrophic condition of the filiform papillæ giving the centre of the tongue in its anterior third an appearance like a black dog s matted coat The use of antibiotics may aggravate it by encouraging the growth of yeasts in the interpapillary spaces The non hairy black tongue may be caused by chewing tobacco or tooth paste dyed sweets certain drugs chromogenic bacteria fungi or metallic sulphides The tongue is dark in Addison s disease

Tumours of the tongue include papilloma carcinoma hæmangioma and lymphangioma lipoma fibroma sarcoma chondroma and mucous cysts

Macroglossia occurs in primary systemic amyloidosis and lingual keratoses in some cases of Darier s disease

BRIAN F RUSSELL

TROPICAL SKIN DISEASES

Introduction —*In the tropics and subtropics skin diseases* are of major importance In addition to those which are peculiar to hot countries the skin diseases of temperate climates are commonly encountered there and for a variety of reasons often assume more serious significance This was very evident in white troops fighting in the tropics in the War of 1939–1945

Skin texture and pigmentation are important, and generally fair skinned blond individuals do not stand hot climates as well as dark complexioned people Albinism and acquired leucoderma are both associated with lack of protective pigment in the skin and depigmented areas especially in fair complexioned individuals and may

Scurvy causes swelling redness and friability of the gums and purpura or hæmorrhage In *pellagra* the tongue is centrally stippled beefy and raw at the narrow tip and sides In *leukæmia* and *agranulocytosis* there may be purpura hæmorrhages and secondary infection, in *pernicious anæmia* the tongue is smooth and glazed, in *hæmophilia* hæmorrhages may occur within the mouth In untreated *diabetes mellitus* the tongue is large red dry glazed and fissured and there may be gingivitis In *uræmia* there may be oral ulceration and gingivitis *Lichen planus* has been described elsewhere buccal lesions occur most commonly and the lips gums and tongue may also be affected in this malady *Lupus erythematosus* occasionally affects the mucosal aspects of the cheeks, there are shiny red eroded areas with ulceration and leucoplakia

Erythema multiforme (see p 1257)

Pemphigus (see p 1288)

Behcet's syndrome begins with ulceration of the mouth ulceration of the genitalia or serious eye changes of conjunctivitis keratitis or hypopyon iritis One site may be affected months or years before the others There may also be nodules in the skin or acuminate papules The eye changes end in blindness The cause is unknown and there is no effective treatment Before the eyes are affected it is doubtful if this malady differs from periadenitis mucosa necrotica recurrens of Sutton or from ulcus vulvæ acutum recurrens of Lipschutz both of which are described as causing ulceration of the mouth and vulva

Epidermolysis bullosa of the skin may be accompanied by eroded oral lesions which go on to leucoplakia

LEUCOPLAKIA

Leucoplakia (mucosal dyskeratosis) is chronic stomatitis

Ætiology and Pathology —Leucoplakia may be caused by physical or chemical irritation or it may be the result of various diseases within the mouth including lichen planus lupus erythematosus syphilis or drug intoxications

Histologically there is hyperkeratosis and parakerato is and slight acanthosis

Clinical Picture —Leucoplakia may be smooth irregular or verrucose The smooth type is common on the buccal mucosa and is relatively benign but on the lower lip it may be the precursor of carcinoma The irregularly raised and depressed form is often syphilitic and precancerous It occurs especially on the tongue and within the angles of the mouth The verrucose form also is potentially carcinomatous The habit of cheek chewing may cause a pseudoleucoplakic roughness and whitening just within the commissure

Diagnosis from lichen planus is sometimes difficult and in fact may not be possible even on histological grounds Lichen planus usually presents as polygonal white spots feathery streaks or foliate traceries and atrophy with slight depression of the surface is more likely to be present than elevation as in leucoplakia At the vulva leucoplakia may be secondary to friction Friction may also cause a white peeling condition with fissuring of the perineum and perianal region this however is not leucoplakia but lichenification modified by the moist flexural situation Leucoplakia only occurs on mucous surfaces The distinction is important because it is unnecessary to excise the white skin of the perineum and perianal region in such a case on the grounds that it is a precancerous condition on the skin as well as on the vulva Excision if it is carried out should be limited to the mucosa of the vulva

Treatment —Leucoplakia is best treated by bland applications such as normal saline mouth washes and hydrous ointment to the vermilion surface of the lip Smoking hot drinks and condiments are best avoided No further action is necessary except periodic inspection for the earliest evidence of neoplastic proliferation If this is seen excision of the affected area should be carried out forthwith Radiotherapy is inadvisable

and yeast like fungi have been incriminated but they are only merely secondary invaders According to O Brien sebaceous deficiency causes physical changes and closure in the keratin ring surrounding the sweat duct occlusion follows and rupture of the sweat duct and the formation of miliarial vesicles ensue each sweat gland involved is said to remain obstructed for some time after the acute attack has subsided

Symptoms —The eruption consists of small glistening superficial vesicles with a well marked red areola and inflamed red papules which feel like grains of sand it may involve the trunk limbs forehead and almost any part of the body The *pricking burning sensation and great itching may be sufficient to prevent sleep, and* secondary bacterial infection may result from scratching

O Brien records that repeated attacks of prickly heat may lead to extensive chronic sweat gland obstruction and tropical anhydrotic asthenia

Treatment —PREVENTIVE —Previous suntan, loose clothing and working or sleeping in air conditioned rooms or in the open air reduce the liability to prickly heat Only light clothing should be worn and when possible it should be changed twice daily Soap should be used with moderation when washing

CURATIVE —After a tepid bath the application of corrosive sublimate solution (1/1000) containing Eau de Cologne is helpful Alternatively the following lotion is useful ℞ acid salicyl gr 30 hydrarg perchor gr 2 Sp vini rect 2 oz Aq dest ad 6 oz Subsequently a dusting powder such as zinc oxide boracic acid and starch in equal parts or boracic acid and menthol, affords some symptomatic relief In chronic cases O Brien advises desquamation of the stratum corneum by daily applications of 10 per cent salicylic acid in 90 per cent alcohol for 2 or 3 days followed by inunctions of lanoline twice daily, and later once weekly to restore the lipoid deficiency

CRAW CRAW

A West African native name (Kra kra) applied to any itchy papular or pustular eruption of the skin

Ætiology —O Neill found filarial embryos in this eruption resembling scabies but they were probably *Microfilaria streptocerca* which Macfie has since commonly found in the skin of West African negroes There is still doubt regarding its ætiology

Symptoms —The papules are hard and horny occur chiefly in the limbs and are very itchy scratching and secondary infection lead to a pustular dermatitis with enlargement of adjacent lymph glands

Diagnosis —The condition must not be confused with scabies or coolie itch no acari are obtained and no burrows seen Cutaneous onchocerciasis has also to be differentiated

Treatment —Pustules are opened ulcers scraped and crusts removed then dis infected with 1 in 1000 sublimate solution or carbolic lotion and subsequently dressed with boric acid ointment

DESERT SORE

Synonyms —Veldt Sore

Definition —A chronic septic sore somewhat resembling impetigo contagiosa occurring on exposed hairy parts of the body and affecting individuals living in hot dusty arid regions the causative organism is generally a hæmolytic streptococcus

Ætiology —The disease has a widespread geographical distribution in hot dry, sandy or desert country being known as veldt sore in South Africa barcoo rot in Northern Australia and desert sore in Egypt Mesopotamia and Iraq where many thousands of troops acquired the disease in the War of 1914–1918 It was equally prevalent in the campaigns in Egypt Palestine and the Western Desert (1940–1943),

show abnormal cutaneous response to sunlight with vesicular inflammation Bright tropical sunlight is especially injurious in conditions of solar sensitivity such as lupus erythematosus Leucoderma has often a peculiar and sinister significance in dark skinned people not only on account of the great disfigurement it produces but also because of its superficial resemblance to the depigmented patches of nerve leprosy

Owing to the heat and humidity a considerable strain is placed on the sweat glands The relatively alkaline reaction of sweat favours secondary pyogenic infection as does the friction of soiled, sweat sodden clothing In arid desert country the skin becomes clogged with dust and the bites of blood sucking insects are specially prone to be associated with secondary bacterial infection Skin diseases which are often regarded as a contraindication to tropical service include severe ichthyosis, lupus erythematosus prurigo æstivalis seborrhœic dermatitis severe acne vulgaris leucoderma and psoriasis (Fergusson) Severe and recurrent attacks of miliaria rubra may necessitate the sufferer abandoning the tropics So may extensive tropical *anhidrosis which is characterised by a goose fleshlike* appearance of the *skin with* local failure of sweating O Brien regards this condition as resulting from chronic occlusion of the sweat glands following successive attacks of miliaria rubra and records that if more than 50 per cent of the sweat glands be blocked in this fashion a state of tropical anhidrotic asthenia results

Certain drugs which are used mainly or exclusively for the treatment of tropical disease may give rise to rashes The use of photosensitising drugs should be avoided *and the possibility of aggravating acne remembered* when using *emetine* bismuth iodide in amœbic dysentery The employment of mepacrine to prevent malaria may occasionally lead to tropical lichinoid dermatitis, it indicates an idiosyncrasy to the drug the administration of which should cease

The tendency for urticaria eosinophilia and other allergic manifestations to develop in individuals with systemic helminthic infestations should be always remembered Parasitic invasion of the skin may be associated with skin eruptions such as ground itch caused by ankylostome larvæ and swimmer s itch' by bilharzia and other cercariæ Similarly creeping eruption may result from migrating larvæ such as *Ankylostoma braziliense* or the larvæ of bot flies of the genus Gastrophilus Warbles or furuncle like lesions discharging fly larvæ may be produced by flies of the genus Hypoderma or Gastrophilus laying their eggs under the dermis

A variety of fungoid infections is common *in the tropics Their course* is liable to be complicated by secondary pyococcal infection and parasitic achromia due to depigmentary action of the fungus Secondary leucoderma is not uncommonly seen in fungoid infections in dark skinned natives

Again native customs may modify such conditions as keloid which is very prevalent in parts of Africa where the negroes often purposely irritate *wounds to* produce tribal markings of a keloid nature

Certain skin diseases *specially prevalent in or peculiar* to the tropics and sub tropics which have not been considered in previous sections are described below

PRICKLY HEAT

Synonyms —Miliaria rubra Lichen tropicus

Definition —Prickly heat is an acute form of heat rash associated with excessive sweating in hot humid climates

Ætiology —It particularly affects Europeans of obese diathesis has a predilection for the covered parts of the skin *especially where there is friction from the clothes* and rapidly disappears on leaving the tropics by aeroplane or in cool weather Probably *it results from* a mechanical blockage of the ducts of the sweat glands with keratin or sodden inadequately cornified cells of the stratum corneum Bacteria

deep ulcers exist in the vicinity of joints The sores should be cleansed treated with a 1/1000 solution of aminacrine (5 amino acridine) and covered with non adhesive dressing such as " tulle gras ', which is coarse curtain net impregnated with petroleum jelly (99 per cent) and balsam of Peru (1 per cent) The application of Flavogel—a water soluble preparation of aminacrine in starch and tragacanth—is a satisfactory alternative treatment Dressings should not be done more frequently than once daily and small sores may be strapped and left much longer In the large chronic ulcers skin grafting is indicated to reduce the time of healing Septic complications such as cellulitis call for the usual treatment and oral sulphonamides or penicillin are indicated when there is evidence that streptococcal infection is spreading to surrounding tissues or lymph glands Diphtheritic sores are a special problem Skin grafting combined with large doses of penicillin and diphtheria antitoxin parenterally produce the best results

TROPICAL ULCER

Synonyms —Ulcus tropicum Naga sore Phagedenic ulcer, Tropical sloughing phagedena

Definition —Tropical ulcer is a gangrenous sloughing ulceration of the skin and subcutaneous tissues which may inolve underlying muscle tendons or bones it generally occurs in the humid tropics runs an intractable chronic course, fusiform bacilli and spirochætes are frequently demonstrable in the discharges

Ætiology —In contradistinction to desert sore this disease is generally, but by no means always confined to the damp steamy tropical jungles occurring most often within latitudes of 35 N 10° S It is common in underfed debilitated and diseased populations may affect people of any age and either sex, and occasionally assumes epidemic proportions especially amongst coolies or native labourers on the plantations and native tribes who eat a vegetarian diet containing only protein of low nutritional value Meat and fish eating tribes are rarely affected and outbreaks among the Somalis occur when the supply of camel s milk is low Some have regarded deficiencies in vitamin D, calcium nicotinic acid and riboflavine as factors in its development All agree that skin trauma is essential and that malnutrition and lack of personal cleanliness predispose to the condition

F fusiformis and spirochætes are commonly demonstrable in the ulcer (70 per cent) and less frequently staphylococci streptococci and bacilli of various types The condition is directly transmissible by inoculation of ulcer pus from man to man or the direct application of pus to the scarified skin over the external malleolus it is also recorded following the direct inoculation of anærobic cultures of *F fusiformis* into a traumatised area of dermis Though the ætiology remains doubtful the available evidence indicates *F fusiformis* is the probable cause

Pathology —There is coagulation necrosis and sloughing of the skin and subcutaneous tissue and separation of the slough leaves a foul acute ulcer with an adherent yellow base Vascular changes are said to occur even early in the disease and to consist essentially of thickening and narrowing of the lumina of vessels which may sometimes be obliterated and sometimes recanalised arteries veins and capillaries are all to some extent implicated (Golden and Padilla)

Symptoms —Phagedenic ulcers generally occur on the dorsum of the foot and the lower two thirds of the front of the legs The thighs the hands and forearms are rarely affected Ulcers are generally single but may be multiple and old scars indicating previous lesions may be present

The disease originates as a sero sanguineous bleb which soon ruptures leaving a dirty grey slough This process rapidly extends forming a foul sloughing ulcer with granulation tissue sides and adherent yellowish grey base which may attain several inches in diameter and gives rise to considerable pain and perhaps intermittent

where it caused considerable loss of manpower Laboratory and field investigations then indicated that the sores were due to infection of the skin following minor injury such as scratches abrasions and insect bites on exposed parts of the body The infecting agent was almost invariably a hæmolytic streptococcus often associated with a pyogenic staphylococcus (Keogh *et al*) In one or two minor outbreaks virulent diphtheria bacilli were isolated, but this finding is infrequent the cutaneous infection probably originated from latent or patent faucial or nasal diphtheria in the first instance Nor was there any discoverable relationship between these sores and deficiency of vitamin C in the rations, or latent scurvy as measured by urinary excretion tests The origin and persistence of these sores were largely connected with the difficulty of keeping the skin clean in a hot and dusty climate when arduous physical work had to be performed and little opportunity existed for bathing washing clothing or sterilising blankets Often the troops were crowded together under conditions when droplet spray infection of clothing and skin would occur some 7 per cent of troops harboured in their throats the same serological types of hæmolytic streptococcus as were isolated from the sores

Symptoms—The desert sore commences as a small vesicle or group of vesicles *containing clear fluid which soon becomes turbid and yellow* The lesions are situated on the dorsum of the hand and forearm and elbow when sleeveless shirts are used or the sleeves rolled up, around the knees and on the thighs when shorts are worn and they also occur on the dorsum of the feet the ankles legs and face The vesicles which are painful and surrounded by a dull red erythematous zone soon rupture and a circular or oval punched out ulcer is formed Its base, which is composed of granulation tissue exuding yellowish green pus is often covered by dark grey pseudo membrane which rapidly re forms if separated The edges are dull red at first but later bluish in colour In some instances undermining occurs and the ulceration may rapidly extend into fresh tissue at a time when the ulcer appears to be healing satisfactorily Desert sores are generally multiple they may cause considerable pain and lead to deterioration in general health especially if septic complications ensue They may take months to heal and often leave a thin scar Septic complications include cellulitis lymphangitis, adenitis bursitis and septicæmia

In those comparatively rare outbreaks in which true virulent diphtheria bacilli are demonstrable in the local lesions faucial diphtheria and carriers are generally prevalent and the cutaneous diphtheria has probably originated from droplet spray *infection of traumatised skin Diphtheritic palsies* such as paralysis involving the palate arms legs iris and muscles of accommodation were recorded in the War of 1914–1918 In campaigns in Palestine and the Western Desert a few such cases were encountered in the War of 1939–1945 but it was always doubtful whether the exotoxin causing such paralyses had been derived from the cutaneous membrane or from coexisting unsuspected faucial or nasal lesions

Treatment—PROPHYLACTIC—Efficient prophylaxis depends on prevention of *skin infection by personal hygiene and adequate first* aid treatment of minor skin traumata Bathing or a bath or shower after the day s work adequate changes of well washed clothing and sterilisation of sheets and blankets are important The surrounding skin area should be shaved the wound epilated and washed with a disinfectant soap or 2 per cent freshly prepared lysol solution followed by methylated spirits or iodine Elastoplast should then be applied and left *in situ* some 4 to 7 days

CURATIVE—*If seen in* the vesicular stage the vesicle should be pricked with a sterile needle the raised skin cut away hairs in the sore removed and a *moist eusol* dressing or diluted ammoniated mercury ointment applied Ambulatory patients who have resisted treatment those with multiple deep ulcers or sores around the ankle elbow and knee joint where movement prevents healing and those in which septic complications have ensued should be admitted to hospital for treatment. *Rest is an im*portant factor in the recovery of such patients and splinting may be necessary if multiple

(1) *Tinea cruris* or dhobie s itch (2) Hong Kong foot or ringworm of the foot (3) *T unguium* (4) *T imbricata* The first two are due to the *Trichophyton Epidermophyton inguinale* they are not peculiar to warm climates and are described elsewhere (pp 1236 1237)

TINEA UNGUIUM —A mycotic infection of the nails affecting Europeans from the Far East it may last for years and be associated with ringworm elsewhere The nail bed is involved leading to brittleness ridging and opaqueness of the nail Diagnosis is made by demonstrating *Epidermophyton inguinale* in scrapings mounted in liquor potassæ The application of a 2 per cent watery solution of copper sulphate or treatment with X rays may prove helpful In severe cases the nails may have to be removed before cure is effected

TINEA IMBRICATA (Tokelau) —A form of ringworm mainly indigenous in the Eastern Archipelago and South Pacific and characterised by non inflammatory raised brown spots giving rise to flaky tissue paper scales which are free centrally but attached at their peripheral bases producing a rosette like appearance These circles are about ½ in in diameter and as adjacent ones form they cause a characteristic festooned appearance The fungus *Endodermophyton concentricum* is readily demonstrable in the scales it affects the face, trunk and limbs but the palms soles scalp axillæ and crutch generally escape

The local application of linimentum iodide (B P) chrysarobin ointment (2 per cent) or of resorcin (1 drachm) in tinct benzoin co (1 oz) are curative Clothing should be boiled to prevent reinfection

PITYRIASIS VERSICOLOR or Tinea Flava is common in the tropics producing pale yellowish brown scurfy patches on the pigmented negroid skin especially on the face neck arms and chest Castellani holds that the yellow patches met with in his Ceylon cases differed from the brownish patches long recognised as being caused by *Microsporon furfur* in the European disease and has named the tropical variety Tinea flava and the causal fungus *Malassezia tropica* the black variety which is caused by *Cladosporium mansoni* Castellani calls Tinea nigra

The skin should be washed daily with green soap in spirit followed by the application of a saturated aqueous solution of sodium thiosulphate In severe cases ung hydrarg ammon dil should be applied daily Sterilisation of the clothing is necessary to prevent reinfection

PINTA

Synonyms —Mal de los pintos Caraate

Definition —A skin disease characterised by pigmentation depigmentation and hyperkeratosis caused by the *Treponema carateum*

Ætiology —The disease is found in tropical America and is specially common in Mexico and Colombia It occurs almost exclusively in dark skinned races and is caused by the spirochæte *T carateum* which morphologically resembles *T pallidum* and is demonstrable in the lesions Syphilis however does not appear to confer immunity Transmission probably occurs by direct contact or through flies feeding on open sores

Pathology —So far visceral lesions have not been described In the skin there are mild chronic inflammatory changes with disturbances of the melanophores and thickening of the corium Sections of the early lesions have revealed *T carateum* in the epidermis

Symptoms —The first stage is said to consist of a papule followed by a secondary stage when flat erythematous lesions known as pintids appear The late or tertiary stage is characterised by patches of pigmentation mainly involving the back of the hands and wrists or the feet and ankles and spreading to other parts of the body

fever, toxæmia and anæmia Sometimes there is spreading gangrene, and the ulcerative process involves surrounding or deeper structures like the toe nails muscles blood vessels, nerves and especially periosteum bone and joints Epidemics are recorded in which extension to tendons and bones occur in one third of the cases Three stages are recognisable (1) spreading sloughing ulceration (2) a stage of tissue equilibrium when destruction and growth of granulation tissue are equalised and (3) healing Often these ulcers persist for months unless properly treated one factor delaying healing is inadequate epithelial proliferation even after a healthy granulation tissue base has formed Excessive fibrosis and adhesion of scar tissue to bone is another cause of failure

Prognosis—Ulcers generally heal with modern treatment but the time taken varies with the facilities available for treatment the size and condition of the ulcer and the resistance of the patient In acute fulminating cases unless penicillin be available death may occur from toxæmia or septicæmia and amputation may be necessary to save life

Treatment—PREVENTIVE—In Europeans protection of the legs with gaiters or puttees is advisable in jungle countries and shorts should not be worn First aid treatment of minor skin traumata is essential A well balanced diet would probably prevent epidemics developing in native populations

CURATIVE—Continuous rest in bed is desirable but is frequently not practicable with natives the leg may have to be tied to some fixed apparatus to enforce this A well balanced nutritious diet adequate in high class protein and vitamins should be given any existent vitamin deficiency should be treated Cod liver oil calcium and certain vitamins of the B_2 complex have been specifically advocated

In the rapidly ulcerating stage complete debridement is an essential preliminary to any treatment Sloughs should be removed and the ulcer irrigated—preferably by diluted hydrogen peroxide Various treatments have been advocated Antiseptics such as carbolic copper sulphate eusol and proflavine have been widely used in the past a paint consisting of copper sulphate 2 drachms phenol 1 drachm glycerin 1 oz has proved useful Others prefer the application of hypertonic or isotonic magnesium sulphate to clean the ulcer Alternative treatments which have the advantage of avoiding daily dressings are to apply Z I P P to the ulcer and then put the leg up in a plaster cast (Cornell and Buchanan) or to firmly bandage with Elastoplast after dusting with iodoform powder Should septic dermatitis develop other treatment must be substituted without delay

The most promising of all recent treatments is penicillin In Europeans and in acute fulminating cases this should be given intramuscularly in appropriate dosage but this routine is generally not feasible in natives both on account of expense and because they object to multiple injections Excellent results have been reported with local penicillin applied as a powder in solution on gauze dressings or as a cream It should be continued for 2 or 3 days after fusiform bacilli and spirochætes have disappeared and the ulcer has become clean Oral chlortetracycline and chloramphenicol have recently been used successfully especially in early lesions which heal rapidly under such treatment and do not frequently relapse *Chlortetracycline* 500 mg 3 times a day for 2 to 10 days *Chloramphenicol* same dosage for 7 days

Whatever the treatment once the ulcer has become clean skin grafting including ' pinch grafts accelerate recovery In chronic ulcers where there is much fibrosis and the ulcer base has become adherent complete excision followed by skin grafting may be necessary

TINEA

Ringworm infections abound in the tropics, some being confined to special regions while others are much the same as in temperate climates The chief ones are

section of the nodules situated at the edge of the sore shows infiltration with plasma and round cells containing poorly staining nuclei in which phagocytosed bacilli may occur in clumps The granulomatous tissue is very vascular while in the older areas fibrosis and scarring are marked Spread is by direct continuity and the lymphatic system is never involved

Symptoms —The disease begins on the genitals as a flat papule which desquamates leaving a red granulation tissue surface which bleeds easily this superficial ulceration extends serpiginously producing offensive pus As the process advances the older areas cicatrise but this scar tissue readily breaks down again The disease is auto inoculable so that adjacent parts such as the scrotum and thighs or the surfaces of the labia become infected Ultimately the whole of the penis scrotum and groins *in the male* and the clitoris vulva labia vagina perineal and perianal region in women become involved and if unchecked the urethra and rectum as well Though skin ulceration extends slowly over a period of many years the process accelerates once the mucous membranes are involved and here there is little tendency to heal Until the terminal phase the general health remains good and the local lesions give rise to a minimum of pain and discomfort

Complications —These include recto vaginal fistula urethral stricture septic cystitis and pyelitis The lymph glands are only implicated if there is secondary coccal infection Cicatrisation may block the lymphatics and cause pseudo elephantiasis of the genitals

Diagnosis —Ulcerations due to syphilis tubercle or lupus vulgaris may be confused and where the glans penis is involved with fungating granuloma epithelioma may be suspected

Prognosis —This has greatly improved by modern treatment formerly the condition was hopeless frequently lasting for life

Treatment.—PREVENTIVE —As the disease is generally contracted by illicit intercourse with native women this should be avoided or appropriate prophylactic measures taken

CURATIVE.—Formerly the trivalent antimony compounds like tartar emetic Anthiomaline and stibophen (Fouadin) were widely employed and regarded as specifics Intravenous injections of tartar emetic were administered as in schistosomiasis (p 321) only a longer course of injections and a greater total dosage was given *i e* gr 50 to 150 Streptomycin chlortetracycline and chloramphenicol have proved considerably more satisfactory than antimonials in treatment Most cases even those resistant to antimony respond to these antibiotics and surgical excision and skin grafting should not be necessary *Streptomycin* 1 0 g intramuscularly every 6 hours for 5 days will cure most cases Pain is relieved in 24 to 48 hours in most cases and healing takes place within 4 weeks Relapses after streptomycin therapy are few and will usually respond to further treatment with this antibiotic, or to chlortetracycline or chloramphenicol *Chlortetracycline* 250 mg orally every 6 hours may be given until healing is complete A total dosage of 15 to 20 g is usually required *Chloramphenicol* up to 3 0 g orally per day may be given in divided doses Dosage for 10 to 12 days is usually adequate

BRIAN MAEGRAITH

The patches are generally symmetrical rough, dry and raised they vary in colour and progress finally to leucoderma Hyperkeratosis also is liable to involve the palms and soles There may be considerable itchiness and, if fissuring occurs an offensive serous discharge is liable to result The Wassermann and Kahn reactions are generally positive in the later stages of the disease

Treatment —The treatment is similar to that of syphilis neo salvarsan and similar arsenical drugs being specifics

PIEDRA

Piedra or trichosporosis is a disease common in Columbia and British Guinea in which hard gritty, black nodosities form around the hair of the scalp it is caused by the *Trichosporon giganteum* and may be confused with ordinary Trichomycosis nodosa

CREEPING ERUPTION

Synonyms —Larva migrans, Myiasis linearis, Hautmaulwarf

Definition —A peculiar linear slightly raised red eruption gradually creeping forward in a sinuous or straight line the posterior end fading away

Ætiology —The condition may be produced by *Gastrophilus* or other fly larvæ wandering under the skin but more commonly it is due to filariform larvæ of the cat and dog hookworm, *Ankylostoma braziliense* which have accidentally invaded man

Symptoms —The symptoms vary in different individuals and include smarting pain and intense itching along the raised line which first shows red spots and later hard round red papules 2 to 5 mm in diameter vesiculation or pustulation may occur Unless treated the condition persists for a long time

Treatment —Freezing the anterior end of the line where the larva is located with an ethyl chloride spray for 2 minutes is suitable for the type due to canine ankylostomes Oleum chenopodii applied locally either pure or diluted with 3 parts of castor oil has been favourably reported on If the lesions are produced by fly larvæ the skin should be dried cleaned with alcohol and cleared with cedar wood oil By means of a hand lens the larva can be seen as a spherical white mass at the end of its burrow Novocaine should be applied before local cauterisation

ULCERATING GRANULOMA

Synonyms —Granuloma venereum, Granuloma inguinale Granuloma inguinale tropicum, Ulcerating Granuloma of the Pudenda Serpiginous Ulceration of the Genitals

Definition —A very chronic ulcerating condition of uncertain ætiology occurring in the tropics involving the genitals perineum and groins

Ætiology —The disease occurs in the West Indies Guiana Brazil Puerto Rico parts of India and Africa the Pacific Islands and Northern Australia Both sexes are affected but not before puberty and all races are susceptible Donovan and many other observers have found a short oval bacillus specially located within the mononuclear cells it is a non motile capsulated bacterium of the rhinoscleroma group but though found with frequency in the lesions there is still doubt as to its real ætiological significance The disease itself is probably contracted during coitus

Pathology —The condition resembles an infective granuloma and microscopic

merely to an impairment of the sense of position—the function which those columns subserve—but also to a severe disturbance of the motor functions But the ataxia *which results is clearly produced by the activity of the intact motor structures working* in the absence of adequate sense of position and is an indirect or secondary effect of the lesion which is brought out only when the motor structures come into action

A final group of symptoms are those which we speak of as "*release phenomena*" When the coma of a hemiplegic patient has passed off he is left with paralytic symptoms namely the hemiplegia In a few weeks the paralysed limbs become spastic their tendon jerks increase and clonus makes its appearance These symptoms of persistent over action of intact nervous mechanisms freed by the lesion from the normal control of physiologically superior mechanisms are what are called release' symptoms Such symptoms may persist indefinitely and in some instances may entirely dominate the clinical picture

The symptoms produced by a lesion depend primarily on its localisation, *i e* on the nervous structures damaged by the lesion and from this aspect they are considered in some detail in a later portion of this section (p 1357) But it must be recognised that the symptoms may also be profoundly influenced by the pathological nature of the lesion A suddenly arising lesion such as an arterial occlusion or hæmorrhage or a direct injury is apt to produce a much more severe and definite local disorder of cerebral function than a slowly developing lesion of similar extent Indeed, it is often a matter of surprise to observe the degree to which the brain can adapt itself to structural changes which are brought about gradually Thus the intracranial cavity *may come to accommodate a large new growth which compresses and markedly* deforms the brain without giving rise to any objective symptoms or to any abnormal physical signs discernible on examination It is similarly known that a cerebral or cerebellar abscess is commonly present for some weeks before it reveals its presence by signs or symptoms this is its period of clinical latency

Again a tumour within the brain while it may give rise to symptoms of increased intracranial pressure such as headache vomiting and papillœdema may yield on examination few or no localising signs and this is not necessarily because it is in what is known as a silent area of the brain but simply because the essential nervous elements have not been seriously damaged by it For instance a glioma being a tumour of the interstitial elements may cause a minimal disturbance of observed nervous function even when large regions of the brain of known and specific function are directly involved by it

As another example of the modification of symptoms by the nature of the lesion a general disturbance may follow a local lesion as a result of what is known as *diaschisis* or *shock* We see this mode of disorder in the coma which accompanies a cerebral hæmorrhage In this state the cerebral hemispheres are for the time being out of action as a whole—even those parts not actually damaged by the lesion Such shock symptoms are necessarily transient

Finally we have to recognise that with space occupying lesions within the skull or brain there may ultimately arise indications of local disorder of function of parts of the brain remote from the lesion These may be spoken of as *false localising signs* and may result from such processes as œdema contre coup pressure or interference with the circulation of blood or cerebro spinal fluid

From what has been said it will be apparent that while the first step in neuro logical diagnosis is the recognition of the disorders of function present the localisa tion of a lesion (the topographical diagnosis) and the determination of its nature (the pathological diagnosis) are usually something *more than a simple essay in the* applied anatomy and physiology of the nervous system and that the complete diagnosis calls for a knowledge of the natural history of the different disease processes—that is of the pathology of nervous diseases—and for clinical experience

SECTION XVIII

DISEASES OF THE NERVOUS SYSTEM[1]

INTRODUCTION

THE diagnosis of a case of central nervous disease involves answers in turn to the two questions Where is the lesion? (the topographical diagnosis) and What is the lesion? (the pathological diagnosis)

Where is the lesion?—The central nervous system is not susceptible of examination by direct methods and all that can be examined are the functions of its various parts The first step is to determine as accurately as possible what disturbances of function are present (sometimes called physiological diagnosis) inferences can then be drawn as to what structures in the brain spinal cord or nerves are affected and consequently as to the site of a local lesion In occasional cases confirmatory localising information is obtained by special techniques such as radiographic examination and electro encephalography and in some cases these methods may even provide the only evidence of the location of the disease

What is the lesion?—In endeavouring to determine the nature of the disease present we are in general dependent on information obtained from sources other than the examination of the nervous system namely (1) the history of the case, (2) the general examination of the patient and (3) special tests

(1) In no department of medicine is careful and expert history taking more important The same physical sign has very different significance according to whether it has come on suddenly with moderate quickness or very gradually (2) A general examination of the patient should never be omitted Disease of the lungs heart blood vessels blood liver and abnormalities of the skin are all of great diagnostic significance in relation to nervous disease (3) Of the special tests ophthalmoscopic examination comes first and is always performed at the same time as the functional examination of the nervous system It often provides most important evidence of the nature of the disease The examination of the cerebro spinal fluid and the Wassermann reaction of the blood frequently help to reveal the kind of disorder present Radiographic examination its power now enlarged by special techniques may be equally diagnostic Electro encephalography is a relatively new aid, of which the diagnostic value is gradually increasing

Symptoms and their Modification—This brings us to a brief consideration of the ways in which lesions within the nervous system may disturb its functions The functions of a region of the brain that is directly involved in a disease process may be deranged in either of two ways They may be stimulated to over activity or they may be diminished or abolished We may thus speak of *irritative* or *excitatory symptoms* on the one hand and of '*paralytic symptoms* on the other a Jacksonian fit being an example of the first while hemiplegia is an instance of the second Thirdly impairment or abolition of one function may cause serious derangement of another A lesion of the posterior columns of the spinal cord gives rise not

[1] While this section has been largely rewritten the authors have made use of much of the material of previous editions and desire to express their indebtedness to the original authors The authors also thank Messrs Butterworth & Co (Publishers) Ltd for permission to make use of parts of Dr Purdon Martin's articl [illegible] rosyphilis in *The British Encyclopædia of Medical Practice*

merely to an impairment of the sense of position—the function which those columns subserve—but also to a severe disturbance of the motor functions But the ataxia which results is clearly produced by the activity of the intact motor structures working in the absence of adequate sense of position and is an indirect or secondary effect of the lesion which is brought out only when the motor structures come into action

A final group of symptoms are those which we speak of as "release phenomena' When the coma of a hemiplegic patient has passed off he is left with paralytic symp toms namely the hemiplegia In a few weeks the paralysed limbs become spastic their tendon jerks increase and clonus makes its appearance These symptoms of persistent over action of intact nervous mechanisms freed by the lesion from the normal control of physiologically superior mechanisms are what are called ' release symptoms Such symptoms may persist indefinitely and in some instances may entirely dominate the clinical picture

The symptoms produced by a lesion depend primarily on its localisation *i e* on the nervous structures damaged by the lesion and from this aspect they are considered in some detail in a later portion of this section (p 1357) But it must be recognised that the symptoms may also be profoundly influenced by the pathological nature of the lesion A suddenly arising lesion such as an arterial occlusion or hæmorrhage or a direct injury is apt to produce a much more severe and definite local disorder of cerebral function than a slowly developing lesion of similar extent Indeed it is often a matter of surprise to observe the degree to which the brain can adapt itself to structural changes which are brought about gradually Thus the intracranial cavity may come to accommodate a large new growth which compresses and markedly deforms the brain without giving rise to any objective symptoms or to any abnormal physical signs discernible on examination It is similarly known that a cerebral or cerebellar abscess is commonly present for some weeks before it reveals its presence by signs or symptoms this is its period of clinical latency

Again a tumour within the brain while it may give rise to symptoms of increased intracranial pressure such as headache vomiting and papillœdema may yield on examination few or no localising signs and this is not necessarily because it is in what is known as a silent area of the brain but simply because the essential nervous elements have not been seriously damaged by it For instance a glioma being a tumour of the interstitial elements may cause a minimal disturbance of observed nervous function even when large regions of the brain of known and specific function are directly involved by it

As another example of the modification of symptoms by the nature of the lesion a general disturbance may follow a local lesion as a result of what is known as *diaschisis* or *shock* We see this mode of disorder in the coma which accompanies a cerebral hæmorrhage In this state the cerebral hemispheres are for the time being out of action as a whole—even those parts not actually damaged by the lesion Such shock symptoms are necessarily transient

Finally we have to recognise that with space occupying lesions within the skull or brain there may ultimately arise indications of local disorder of function of parts of the brain remote from the lesion These may be spoken of as *false localising signs* and may result from such processes as œdema contre coup pressure or inter ference with the circulation of blood or cerebro spinal fluid

From what has been said it will be apparent that while the first step in neurological diagnosis is the recognition of the disorders of function present the localisation of a lesion (the topographical diagnosis) and the determination of its nature (the pathological diagnosis) are usually something more than a simple essay in the applied anatomy and physiology of the nervous system and that the complete diag nosis calls for a knowledge of the natural history of the different disease processes—that is of the pathology of nervous diseases—and for clinical experience

DISORDERS OF THE CRANIAL NERVES

THE OLFACTORY NERVE AND TRACT

Small olfactory *nerve filaments arise from special receptors in the olfactory* portion of the nasal mucosa, and joining together into small nerves pass through the cribri form plate of the ethmoid bone to end in the two olfactory bulbs From each olfactory bulb an olfactory stalk passes backwards on the inferior *surface of the frontal lobe of* the brain and ends in two roots lateral and medial, on either side of the anterior perforated spot

Loss of the sense of smell (anosmia) is *frequently due to disease of the nasal* mucosa and only occasionally is it of diagnostic value in cases of nervous disease or injury It occurs in cases of head injury especially if the patient has fallen upon his forehead or upon his occiput and is usually due *to tearing of the olfactory nerves,* with or without fracture of the cribriform plate In most cases the loss of smell is permanent

Unilateral or bilateral anosmia may result *from meningeal* tumours arising from the olfactory groove and pressing on the inferior surface of one or both frontal lobes and it occasionally results from basal syphilitic meningitis

Flavours are actually appreciated by the sense of smell so that a patient who has lost this sense is apt to think that he has lost his sense of taste as well but if the sense of taste is retained he will still be able to appreciate the primary flavours—salt sweet, bitter and acid

THE OPTIC NERVE

The optic nerve is developed as a cerebral tract and retains something of that character throughout life The primary visual neurones are situated entirely in the retina it is the neurones of the second order whose fibres form the optic nerves and tracts *Disturbances of these structures are frequent and are of great importance* in many kinds of nervous disease

The optic nerve head or optic disk can be seen with the ophthalmoscope and is the only *part of the central nervous system which can be examined* by inspection Congenital abnormalities of the optic disk are not uncommon the most important being the presence of opaque nerve fibres When viewed with the ophthalmoscope a *bundle of opaque nerve fibres is seen* as a glistening white streaky mass appearing to stream out from the nerve head into the adjacent parts of the retina The fibres may be limited to one quadrant, or may be all round the disk The acquired disturb *ances of the optic nerve* give rise to four principal syndromes (1) papilloedema *(2) optic neuritis or neuro retinitis, (3)* retrobulbar *neuritis and (4) optic atrophy*

PAPILLŒDEMA

The term denotes an œdema of the optic papilla or nerve head, and the significance of such œdema lies in the fact that it is almost invariably due to raised intracranial pressure it is frequently the only objective sign of that state, and it is important that the student should be familiar with it in all its stages Before there is any actual œdema of the optic nerve head the principal veins of the retina may appear distended and the disk appears somewhat redder than its normal colour *Then the margin of* the disk becomes blurred in its upper and inner quadrant or in its uppermost portion this blurring extends around the disk and at the same time the cup of the disk becomes filled up The disk becomes *much redder* than normal and may be of almost the same colour as the retina The disk continues to swell and bulges slightly into the

eye and this swelling can be measured with the opthalmoscope relative to the surrounding retina in terms of dioptres a swelling of 4 dioptres is common but higher degrees of swelling are rare As the swelling increases the disk margins become still more blurred and some hæmorrhages and exudate may appear With the increase of swelling the arteries appear to sink down as they pass off the disc on to the retina and the retina close to the disk especially on the macular side may show some swelling or tendency to fold When the rise of intracranial pressure is slow the œdematous disk is less highly coloured than when the pressure rises quickly and the œdema is more acute In the early stages of papillœdema there is little disturbance of vision but when the swelling becomes severe the patient begins to complain of some blurring of vision and of transitory severe disturbance of sight (amaurosis fugax) associated with stooping or with physical effort

If the intracranial pressure is high and is not soon relieved the sight eventually fails the disk becomes paler and takes on a somewhat waxy appearance and gradually subsides into atrophy This consecutive ' or ' post neuritic atrophy can in many instances be recognised ophthalmoscopically by the irregularity of the edges of the atrophied disk consequent on the preceding swelling and exudation

OPTIC NEURITIS AND NEURO RETINITIS

Actual inflammation of the nerve head is rare but the abnormal state of the disk and retina that is associated with renal disease with arterial hypertension is often mistaken for papillœdema due to raised intracranial pressure The disc is blurred and usually slightly swollen the swelling of the disk however rarely exceeds 2 dioptres while the changes in the retina are pronounced and extensive and are much greater than those that may be associated with papillœdema

RETROBULBAR NEURITIS

This term is applied when disease regarded as inflammatory affects the optic nerve behind the papilla and as a rule the disease is situated farther back than the point about half an inch behind the eye where the central vein emerges from the optic nerve

Local lesions in the substance of the nerve between the globe of the eye and the chiasma are very common and according to their severity give rise to partial or complete blindness in the corresponding eye As the central part of the optic nerve is the site of election for such lesions the visual defect is commonly in the form of a central scotoma This is the characteristic disturbance and is usually acute or subacute in its onset but there are a number of associated phenomena The patient frequently complains of pain on movement of the eyeball and sometimes of pain above the eye The fundus of the eye usually looks normal but when the disease comes forward to the papilla redness of the optic disc and blurring of its edges may be apparent The pupil is usually moderately dilated, it reacts to light but often does not maintain the reaction These associated phenomena soon pass off and in most cases the central scotoma begins to diminish within a few weeks The prognosis depends however on the cause of the syndrome

Disseminated sclerosis is the usual cause of acute retrobulbar neuritis With this condition the disturbance is almost invariably unilateral and a great degree of recovery is the rule Functional recovery may be complete in other cases a central scotoma for colour or a small absolute central or paracentral scotoma is left Characteristically a slight degree of optic atrophy follows causing permanent pallor of the temporal half of the optic disc

Bilateral retrobulbar neuritis occurs from toxic causes and also occasionally without discoverable cause and the outlook for recovery of vision in such cases is

always doubtful The less severe toxic cases are usually due to tobacco, more severe disturbances are due to such causes as poisoning by wood spirit present in alcohol by arsenical compounds such as tryparsamide, by lead compounds and by quinine Retrobulbar neuritis may also be bilateral in neuro myelitis optica, a rare demyelinating disease closely resembling an acute form of disseminated sclerosis Leber's disease is a familial malady characterised by retrobulbar neuritis, males only are affected and the symptoms make their appearance after puberty and usually before the age of 25 Repeated attacks may occur and a severe degree of optic atrophy result

OPTIC ATROPHY

Optic atrophy is recognised on ophthalmoscopic examination, by a peculiar whiteness and flatness of the disk with a very high contrast at the edge of the disk between disk and surrounding retina both as regards colour and limitation The lamina cribrosa—the sieve like cross latticing of the strands of the sclerotic through which the bundles of optic nerve fibres pass—becomes visible as a stippling of the temporal region of the disk The vessels of the retina become atrophied, and are seen *to be unduly small* In many atrophies the edge of the disk is sharply cut but when atrophy follows papillœdema the edge is apt to be fluffy like that of torn cotton wool Optic atrophy is usually classified as primary or consecutive, according to whether the atrophy of the disk is the first observable change or follows upon papillœdema or inflammation of the disk or optic nerve

Ætiology—*Primary optic atrophy*—1 This is of frequent occurrence in the hereditary or congenitally installed diseases in which primary degeneration of neurones occurs and in particular it occurs in association with the hereditary ataxias In amaurotic family idiocy and retinitis pigmentosa, both of which are familial diseases optic atrophy is consequent upon degeneration of the neurones in the retina 2 It *is one of the common manifestations of syphilis of the nervous system* and may occur alone but much more usually it occurs as part of the syndrome of tabes or of general paralysis It is not uncommonly met with in congenital syphilis 3 It results from lesions of the optic chiasma and optic nerve and is the constant result of long continued pressure upon these structures This variety often called *retrograde optic atrophy* is usually due to pituitary and other tumours in the neighbourhood of the chiasma, and occasionally to tumours aneurysms or bony injuries behind or involving the optic foramen It also results from local disease within the orbit 4 It may follow the exhibition of certain drugs such as tryparsamide methyl (wood) alcohol, quinine 5 It may result from severe hæmorrhage from any part of the body or from anæmia and may occur in association with pernicious anæmia and subacute combined degeneration of the spinal cord Optic atrophy may also result from diabetes arterial disease (with or without thrombosis of the central artery of the retina) and from glaucoma

Consecutive optic atrophy—1 This follows the more severe grades of papillœdema and is due to strangling of the optic nerve fibres by the œdema in the first place and by the cicatrisation subsequently Severe degrees of papillœdema may if pressure be relieved recover perfectly without atrophy or impairment of sight 2 It follows inflammation of the optic nerve and in occasional cases is seen in the late stages of the neuro retinitis associated with arterial hypertension 3 Partial optic atrophy of varying degree is an almost constant result of retrobulbar neuritis

THE OCULO MOTOR NERVES

The third nerve supplies the internal muscles of the eye and all the external muscles of the eyeball with the exception of the superior oblique (which is supplied

by the fourth nerve) and the external rectus (which is supplied by the sixth nerve) Complete paralysis of the third nerve produces a dilated and inactive pupil complete ptosis and loss of upward downward and inward movements of the eye the eye assumes a position of downward and outward strabismus As a rule diplopia is not complained of because of the dropping of the lid Many third nerve palsies are, however partial, and the muscles innervated by the nerve may be affected in different degrees When diplopia is present it is a crossed diplopia because the strabismus is divergent there is secondary deviation of the sound eye and false projection in the visual field

The fourth nerve supplies the superior oblique muscle Paralysis produces no obvious strabismus but in looking outwards or downwards there is a wheel movement of the globe which can be detected by observing the conjunctival vessels when the eye moves The diplopia is most discomforting and occurs in every position of the eyes except on looking up The diplopia is uncrossed and the false image is lower than and with its top tilted toward the true image

The sixth nerve supplies the external rectus muscle Paralysis of it produces a convergent squint and uncrossed diplopia

These oculo motor nerves may be affected singly or in various combinations and the paralysis of any one of them may be complete or partial In some cases the lesion responsible for the paralysis lies within the brain stem where it may affect either the nuclei of the nerves or the nerve fibres in their intra cerebral course More often the lesion affects the nerve in its peripheral course—within the cranium in the neighbourhood of the sphenoidal fissure or within the orbit To attempt to give a list of all the possible lesions—inflammatory neoplastic hæmorrhagic or traumatic—that affect these nerves would serve no useful purpose but the following may be noted and certain syndromes should also be recognised Syphilis is a common cause of third nerve paralysis by involvement of the nerve in syphilitic meningitis less commonly the sixth and fourth nerves are affected by the same process Any of the forms of acute and subacute meningitis may similarly involve one or more of the oculo motor nerves Secondary malignant deposits in the meninges or in the brain stem are not uncommon causes of ocular palsies Primary intracranial tumours and aneurysms may cause paralysis of any or all of them by direct compression but intra cranial pressure of itself may cause paralysis of the sixth nerve as a result of downward displacement of the brain stem Paralyses of the sixth nerve are frequently rheumatic (i e of undetermined cause) or are associated with generalised arterial disease or with diabetes the mechanism of the paralyses in such cases is obscure but recovery within a month or two is the rule A variable ocular palsy or variable diplopia is often due to myasthenia gravis

Syndrome of the sphenoidal fissure —All the oculo motor nerves enter the orbit by the sphenoidal fissure and they are accompanied by the branches of the first division of the trigeminal nerve and the ophthalmic veins while the second division of the trigeminal nerve enters the infra orbital canal at the apex of the orbit All these structures may be involved by a lesion at the sphenoidal fissure the most common causes being aneurysm of the internal carotid artery at the anterior end of the cavernous sinus and meningeal tumour The syndrome usually begins with pain in the eye and forehead Soon afterwards some proptosis is evident and there is pain on pressing the globe backwards This is followed by signs of involvement of the oculo motor nerves The sixth is the first and sometimes the only nerve involved and usually its paralysis is followed by that of the fourth the first division of the fifth the third and sometimes the second division of the fifth in that order The final result may be a total ophthalmoplegia with anæsthesia of the eye corresponding half of the fore head and the cheek severe pain in the same distribution and unilateral proptosis but the syndrome is often incomplete When it is due to aneurysm the condition may largely recover within a few months

The oculo motor nerves may be paralysed in the *wall of the cavernous sinus* either as a result of thrombophlebitis of the sinus or of an aneurysm of the internal carotid artery

Gradenigo s syndrome —This consists of paralysis of the sixth nerve and pain of trigeminal distribution associated with middle ear disease It has been attributed to localised meningitis at the tip of the petrous bone but Symonds has pointed out that it may be due to thrombosis of the inferior petrosal sinus It is usually seen in children, and radical treatment of the ear disease is indicated

Lesions within the brain stem may produce combined oculo motor palsies, other cranial nerves may also be affected or the long projection paths may be involved Finally supra nuclear ocular palsies may arise, as described below Nuclear palsies may result from tumours disseminated sclerosis epidemic encephalitis tuberculoma and small peri aqueductal hæmorrhages The rare condition known as *chronic progressive external ophthalmoplegia* formerly ascribed to degeneration of the oculo motor nuclei is now believed to be due to myopathic disease of the muscles within the orbit This disease may begin in young subjects it is slowly progressive and leads to paralysis of all the external ocular muscles with ptosis which is usually incomplete the internal ocular muscles are unaffected

Oculo motor nerve fibres within the brain stem may be affected by vascular neoplastic and granulomatous lesions Thus a lesion in the cerebral peduncle will produce an ipsilateral third nerve paralysis with hemiplegia on the opposite side of the body (*Weber s syndrome*) and a lesion involving the red nucleus may cause an ipsilateral third nerve palsy with tremor of the limbs on the opposite side (*Benedikt s syndrome*)

CONJUGATE PARALYSIS

The uppermost portion of the main third nerve nucleus is concerned with upward movement of the eyes (superior recti) and the inferior recti are represented next in order from above downward Bilateral lesions involving the upper parts of both nuclei consequently bring about a loss of vertical movements of the eyes the horizontal movements being retained The lowest part of each third nucleus is concerned with the internal rectus muscle and is connected with and partly governed by the sixth nucleus of the opposite side A bilateral lesion at the level of the upper part of the pons by involving these structures may cause paralysis of horizontal movement of the eyes vertical movements remaining unaffected Paralysis of conjugate movements to one side occurs less frequently The power of convergence is sometimes preserved when conjugate horizontal movement is lost

SUPRA NUCLEAR OCULAR PALSIES

In some cases although the patient is unable voluntarily to perform certain ocular movements it can be demonstrated that the muscles and nerves concerned are not paralysed and movements of the eyes can be brought about reflexly by appropriate stimuli The paralysis is therefore supra nuclear and comparable to an upper motor neurone paralysis The patient may be unable to deviate his eyes to order but deviation may be produced by labyrinthine stimulation Or again the patient may be unable to follow a moving object with his eyes but if he fixes an object and his head is rotated passively his gaze may remain fixed on the object and his eyes thus take up a position of deviation In rare cases the eyes when the head is still may follow an object which the patient fixes intently The lesions concerned are believed to be situated in the brain stem close to the oculo motor nuclei

ABNORMALITIES OF THE PUPIL

Myosis or abnormal smallness of the pupil may be due to paralysis of the cervical sympathetic (p 1345) minute pupils are sometimes associated with syphilis of the

nervous system particularly tabes each pupil being possibly little larger than the head of a pin (spinal myosis) myosis occurs also with acute lesions of the pons and it may be met with in advanced age without pathological associations It is a well known sign of the action of morphine and it is produced also by the local action of eserine instilled into the eye

Mydriasis denotes dilatation of the pupil The sphincter pupillæ muscle is controlled by the small nucleus of Edinger Westphal which is the uppermost part of the third nerve nucleus Mydriasis may therefore, result from paralysis of the Edinger Westphal nucleus and more commonly it is one of the features of paralysis of the third nerve It results also from the action of belladonna or atropine—or of cocaine whether taken internally or used as eye drops

Inequality of the pupils has numerous causes Obviously it may result from any of the causes of unilateral myosis or of unilateral mydriasis given in the preceding paragraphs Less specifically it is common in nervous syphilis It may result from a blow on one eye or from disease of the eye It occurs as a transitory phenomenon after the prolonged use of one eye especially against a bright light as in using the microscope It is common with local cerebral lesions of all kinds including closed head injuries It is a feature of cases of intradural and of subdural hæmatoma

Irregularities of the shape of the pupil are less common than inequality of the pupils They may be due to local disease of the irides but in certain cases of disease of the brain stem especially syphilitic disease one or both pupils may be oval in outline without evidence of local disease of the irides Irregularity of the pupils is common in neuro syphilis generally and is frequently associated with atrophic changes in the irides, such as are associated with diabetes

ARGYLL ROBERTSON PUPIL

The normal pupil contracts briskly when light falls upon the eye and dilates in darkness it also contracts in association with accommodation and convergence The reaction to light is reflex and this reflex response to light may be lost when other reactions of the pupil are retained (reflex iridoplegia) In the particular form of reflex iridoplegia known as the *Argyll Robertson pupil* the pupil is abnormal in that (1) it does not react at all to light (2) it is very small and (3) it does not dilate fully under the influence of a mydriatic, while it is normal in that (1) it reacts normally with accommodation convergence also (2) reasonably good vision in the eye concerned is an essential part of the phenomenon Such a pupil is almost invariably due to syphilis of the central nervous system and is seen most frequently and characteristically in tabes dorsalis The phenomenon is ordinarily bilateral, but there are often differences in size between the two pupils and usually the pupils are irregular in outline Atrophic changes in the irides are generally apparent

The afferent fibres of the light reflex arc pass back with the visual fibres in the optic nerve and optic tracts but whereas the visual fibres end in the lateral geniculate body the fibres which serve the light reflex pass on to enter the superior corpus quadrigeminum From there a connection is formed by another fibre with the upper part of the oculo motor nucleus (Edinger Westphal nucleus) The efferent fibres of the reflex arc form part of the oculo motor nerve Since with the Argyll Robertson phenomenon vision is good the visual path is evidently intact and since the pupil contracts with accommodation convergence the cells and fibres of the third cranial nerve which innervate contraction of the pupil must be intact the arc must therefore be interrupted in its middle portion *i e* between the place where the light reflex fibres leave the visual fibres and the oculo motor nucleus Degeneration of the fibres forming this middle portion of the arc is not however easy to recognise by staining methods and this theory still awaits anatomical confirmation

The Argyll Robertson pupil once established persists in spite of antisyphilitic

treatment As the tabetic process advances the accommodation convergence reaction may gradually be lost and the pupil thus ceases to show the dissociation of reactions typical of the Argyll Robertson phenomenon and becomes a fixed pupil

Modifications of the Argyll Robertson pupil are frequently encountered in diseases of the nervous system A slight reaction to light may be present in a pupil which otherwise conforms to Argyll Robertson s description This represents a preliminary stage of the complete phenomenon and its significance is similar

More frequently the pupil reacts normally with convergence and does not react to light but it is not small and may even be dilated Such a pupil is common in central nervous syphilis but has not the diagnostic significance of the complete Argyll Robertson phenomenon *for it may be due to any lesion interrupting the light* reflex arc in its middle portion A pineal tumour for instance or a tuberculoma or a patch of disseminated sclerosis may cause this abnormality and it has been described in association with many different nervous diseases If however atrophic changes are present in the iris the condition is likely to be syphilitic

PSEUDO ARGYLL ROBERTSON OR MYOTONIC PUPIL

Pseudo Argyll Robertson pupil (Foster Moore) or myotonic pupil (Adie) is a non syphilitic abnormal condition of the pupil in which the reactions are all slow *but the light reaction much slower than the convergence reaction The pupil is of* ordinary size or somewhat larger and is usually bigger than the unaffected pupil of the other eye No reaction is obtained to the light of a torch shone on the eye but if the patient sits for 10 or 15 minutes in a bright diffuse light the pupil gradually contracts and if he sits in a dark room it dilates slowly During accommodation convergence contraction of the pupil takes place slowly and continues through an abnormal range of movement so that as convergence is maintained the myotonic pupil finally becomes smaller than its fellow After relaxation of convergence the pupil takes many minutes to dilate to its former size In pupils of this kind prompt and full dilatation occurs with mydriatics

The phenomenon is usually *unilateral and the iris of the affected eye* does not show degenerative changes such as usually accompany the true Argyll Robertson pupil Accommodation may be involved in the disturbance and then the patient complains of inability to focus with the affected eye

Ætiology—The cause of this phenomenon is unknown It is the more likely to be mistaken for a syphilitic abnormality because in some cases it is associated with absence of some of the tendon jerks in the limbs Once established it persists but as far as is known at present it is not associated with any progressive disease

The difference between the true and pseudo Argyll Robertson pupils may be tabulated as follows

TRUE ARGYLL ROBERTSON PUPIL	PSEUDO ARGYLL ROBERTSON PUPIL
Quite inactive to light or darkness	Reacts slowly to light and darkness
Reacts briskly *with convergence*	*Reacts slowly* with convergence
Smaller than normal	Larger than normal
Ordinarily bilateral	Usually unilateral
Usually irregular in outline	Regular in outline
Iris shows atrophic changes	Iris looks healthy
Dilates imperfectly with mydriatics	Dilates fully with mydriatics

PARALYSIS OF THE REACTION WITH ACCOMMODATION

The pupil does not contract when an effort to accommodate is made Accommodation itself may or may not be present *i e* the ciliary muscle may or may not

be acting This condition is most commonly seen as an after effect of encephalitis lethargica, and so is usually associated with the post encephalitic Parkinsonian state

Conversely the ciliary muscle may be paralysed and the patient be deprived of accommodation but the pupil may still contract in association with the effort to accommodate This occurs in diphtheritic paralysis of which it is one of the earliest symptoms and it is said to occur sometimes in tabes It must depend on disease of the centres in the nuclei of the third nerves

In cases of disease of the third nerve the ciliary muscle is paralysed as well as the iris

PARALYSIS OF THE CERVICAL SYMPATHETIC

Synonym —Horner s Syndrome

So far as the eye and orbit are concerned the sympathetic is the tonic retractor of the lid the tonic protruder of the eyeball and the tonic dilator of the pupil and stimulation of this mechanism results in retraction of the lids or widening of the palpebral fissure exophthalmos and wide pupil while paralysis of the cervical sympathetic produces narrowing of the palpebral fissure (cervical sympathetic ptosis) and a small pupil It is customary to include enophthalmos amongst components of cervical sympathetic palsy but in many cases this is not recognisable The excitation is seen in Graves disease the paralytic condition is of common occurrence in nervous diseases The cervical sympathetic is also the tonic vaso constrictor and secreto motor nerve of the head generally but disturbance of this mechanism does not often give rise to characteristic, or important clinical phenomena A curious lack of expression is however sometimes observable in the face on the side of the lesion Cervical sympathetic paralysis occurs in the following clinical associations (1) In many lesions of the brain stem or of the cervical portion of the spinal cord especially when the last cervical and first dorsal segments or roots are damaged It is common in syringomyelia (2) In lesions of the cervical sympathetic trunk by trauma pressure growths etc. (3) It is very common in tabes and nervous syphilis generally where it appears as partial bilateral ptosis with small pupils It appears to be due to a primary neuronic degeneration in this condition and never improves

THE FIFTH OR TRIGEMINAL NERVE

The fifth nerve arises from the pons by a large sensory and a smaller motor portion The sensory portion supplies sensation of all forms to the same side of the face and anterior half of the scalp Its ganglion cells lie in the Gasserian ganglion, which lies *near the apex of the petrous bone and distal to the ganglion the nerve* is in three divisions (from which the nerve derives its name) The first or ophthalmic division passes forward on the wall of the cavernous sinus and enters the orbit in three branches It supplies sensation to the forehead and anterior portion of the scalp to the eye and to the ridge of the nose The second or maxillary division leaves the cranium by the foramen rotundum passes across the spheno palatine fossa and enters the infra orbital canal Having traversed the canal it emerges on the anterior surface of the maxilla half an inch below the lower rim of the orbit and its branches spread out to supply the skin of the cheek and upper lip the mucous membrane of the nose the upper jaw and the hard and mo t of the soft palates The third or mandibular division leaves the cranium through the foramen ovale and enters the infra temporal fossa it is accompanied by the motor root which here unites with it to form a single trunk It supplies sensation to the skin of the lower lip

chin and outer part of the cheek and by its auriculo temporal branch to part of the auricle and to the temporal area it also supplies the mucous membrane of the lower lip lower jaw floor and sides of the mouth and anterior two thirds of the tongue Its lingual branch contains taste fibres from the anterior two thirds of the tongue which however leave it by the chorda tympani nerve and pass over to the facial nerve The motor root of the trigeminal nerve innervates the temporal muscle masseter buccinator, internal and external pterygoids mylo hyoid anterior belly of the digastric and also the tensor tympani and tensor velipalatini

The fifth nerve may be involved in the pons by tumours and not infrequently by disseminated sclerosis the Gasserian ganglion may be irritated or compressed by tumour or aneurysm and it is frequently the site of herpetic inflammation with a consequent herpetic eruption over the area of the external distribution of the nerve most commonly only the ophthalmic division is thus affected (see Herpes Ophthalmicus) Organic lesions of the divisions of the nerve or their branches at first cause pain and then sensory loss with a distribution corresponding to the portion of the nerve involved Loss of the corneal reflex is often the first indication of involvement of the fifth nerve *e g* in cases of acoustic nerve tumour

Paralysis of the motor function of the fifth nerve occurs in lesions of the nucleus in the pons or of any part of the peripheral course of the motor division The signs of such paralysis are not apparent to the patient who experiences no difficulty in mastication provided the lesion be unilateral To the observer the jaw deviates to the side of the paralysis when the mouth is opened on account of the action of the unopposed external pterygoid of the sound side The masseter, as felt by the finger on its anterior edge does not harden on biting nor do the temporal muscles harden and wasting of these muscles may be evident The floor of the mouth does not stiffen on the paralysed side when the mouth is forcibly opened

Bilateral involvement of all the muscles supplied by the fifth nerve is the rule in all cases of progressive muscular atrophy when the bulbar nuclei are affected

TRIGEMINAL NEURALGIA

Synonym —Tic Douloureux

Definition —A malady characterised by paroxysms of intense pain of a sharp stabbing nature within the distribution of the trigeminal nerve without sensory loss or other evidence of organic disease of the nerve

Ætiology —The cause of trigeminal neuralgia in most cases is unknown The vast majority of patients are over 50 years of age and most of them are arteriosclerotic and have high blood pressure Females are affected more frequently than males A number of cases in younger people are due to disseminated sclerosis and there is also a form different from the chronic trigeminal neuralgia of elderly people which occurs temporarily in young subjects from exposure to cold and may recur

Symptoms —The chief feature of the malady is pain which may be general throughout the area of distribution of the nerve but which is more commonly confined to one of the three divisions of the nerve and often to one branch of a division It is characteristic for the pain of neuralgia to commence locally and subsequently to spread in each attack and gradually in the course of the disease permanently to invade a larger area Two different kinds of pain occur the sharp and paroxysmal and the dull continuous pain The paroxysmal pains are sudden in onset and in cessation They have a lightning like character and are described as piercing knife like or as if the affected region were penetrated by red hot wires

Though often quite spontaneous these pains may be brought on by movements of the face and jaw or by touching the surface or by a cold wind The sufferers typically describe them as brought on by eating and talking and washing the face and may wear a scarf round the head to protect the affected side of the face from the

wind Mastication may become so difficult as to render the feeding of the patient a matter of anxiety The paroxysms are brief seldom lasting longer than 1 or 2 minutes but they may recur frequently, and the patients usually describe different degrees of liability to them at different times

When the paroxysms are occurring in a severe case the patient remains for a period which may be from a few minutes to several hours paralysed under the fear of pain unable to move a muscle lest a spasm more dreadful than the last should occur The paroxysmal pains are usually followed if severe by a more lasting dull continuous pain often of a boring character and sometimes such pain becomes absolutely continuous The skin over the affected region is sore and tender after the paroxysm and the patient may be unable to bear brushing the hair or shaving the face The pain may be of every degree of severity from mild momentary starts to continuous incapacitating pain interrupted only by excruciating attacks of agony which render life a burden

The distribution of the pain is usually in one or two divisions of the nerve The first division is rarely affected primarily but pain may spread into it from the second division If the pain begins in the second division it may after a time affect the third and vice versa The lightning like onset of the agony often causes convulsive spasm of the face and of the body and limbs The tender points of Valleix or trigger zones are constantly present during the attack and for some time afterwards When the second division is affected a little œdema develops under the orbit when paroxysms are frequent When the third division is affected unilateral furring of the tongue occurs Fortunately the attacks usually cease at night

Diagnosis—The quality of the pain is characteristic and when trigeminal neuralgia is present the diagnosis is not often missed especially if a paroxysm is witnessed The usual mistake is to regard as trigeminal neuralgia pain that is due to some other cause and since there are very many conditions that give rise to pain in the face the opportunities for error are numerous Unless the pain is brought on by eating and talking and washing the face it is almost certainly not due to trigeminal neuralgia Pain that is constant or of a continuous character is not due to trigeminal neuralgia and some other cause should be sought Disease of the frontal sinus and glaucoma should be kept in mind Local painful neuro es or psychogenic pains are continuous though subject to fluctuation and when at their worst they often spread to the other side of the face as trigeminal neuralgia never does

A similar neuralgia occurs in the glosso pharyngeal nerve but is much rarer the pain is induced by the movement of swallowing and is felt in the ear or throat

Course—In the early stages remissions lasting months or years are usual but in old patients remissions if they occur are likely to be brief In all cases the remissions become shorter as time goes on and unless the affected division of the nerve is destroyed the neuralgia persists for the rest of the patient s life In occasional cases the disease is bilateral

Treatment—In the first place it is essential to make sure that all possible causes of local irritation in the region of distribution of the fifth nerve are absent or if present adequately dealt with Secondly it is important to remember that in its early stages the malady shows complete remissions of long duration These remissions do indeed tend to become shorter after some years but their occurrence suggests that in planning treatment it is essential to consider the circumstances of each individual case Thus if a patient who may be expected to enjoy a long period of freedom from pain can be tided over the present attack by medical means it is clearly not wise to give an alcohol injection immediately

In the hope that remission will occur medicinal treatment should be given a trial provided the pain is not too intense Tinct gelsemii in doses of 10 to 20 minims is an old fashioned and seemingly effective remedy and may be combined with

phenazone gr 10 in solution or aspirin gr 10 in emulsion and with liq arsen min 2 This should be taken regularly three or four times daily when the attacks of pain are prevalent and the number of doses may be reduced when the frequency of pains diminishes

If after a few weeks of such treatment the neuralgia is still severe more effective measures should be employed without delay One affected branch of the nerve may be destroyed temporarily by injection of alcohol into it the corresponding area of the face being thereby rendered anæsthetic The permanence of the relief obtained by a successful peripheral injection varies and is usually longer when the third division is concerned than when the second is the affected one The operation is at all times a tricky one requiring great skill on the part of the operator, and subsequent injections become more and more difficult Alternatively the Gasserian ganglion can in most patients be injected with alcohol but while this gives a permanent result it has the disadvantage that the whole of the affected side of the face is rendered completely anæsthetic including of course the eye in which severe trophic keratitis will quickly develop unless adequate precautions against its occurrence are taken at the time of the injection However injection of the ganglion is an excellent treatment in skilled hands In general the most successful treatment is operative sub total division of the sensory root of the fifth nerve proximal to the Gasserian ganglion This renders the area of the second and third divisions anæsthetic and allows sensation to be retained over most of the area of the first division thus avoiding risk to the eye and the effect of the operation is permanent The practice of different physicians in recommending this operation varies considerably but it has been performed successfully on patients of all ages and the mortality nowadays is low In the case of a patient under the age of 50 years in whom the neuralgia seems established operation should be advised at once since the patient may still have many years of life before him and the neuralgia will never leave him for more than a few months With older patients each case must be considered on its merits

The operation of stripping the dura from the Gasserian ganglion and its immediate vicinity is under trial and has given good results over a short period

THE SEVENTH OR FACIAL NERVE

The seventh nerve supplies all the muscles of the face the platysma and the muscles of the scalp It is a purely motor nerve but the taste fibres which convey taste from the anterior two thirds of the tongue join it by way of the chorda tympani nerve and are incorporated in it for part of its course Fibres which excite salivary secretion are also associated with it at one part

The facial nerve may be paralysed in cases of pontine tumour or hæmorrhage, or in association with tumours or syphilitic meningitis in the cerebello pontine angle or by inflammation or operative intervention in the middle ear it may be paralysed within the facial canal as a result of herpes of the geniculate ganglion inflammation or compression of the nerve within the stylomastoid foramen is the cause of the common Bell s palsy and enlarged glands behind the angle of the jaw or a tumour of the parotid gland or traumatic lesions may be responsible for paralysis of the nerve just before it divides into the branches which distribute it over the face Bilateral facial paralysis not infrequently occurs in acute infective polyneuritis

Paralysis of the face due to a lesion of the facial nerve or its nucleus causes as a rule equal paralysis or uniform weakness of all portions of the affected half of the face If the lesion is in the pons the sixth nerve is usually affected as well When the lesion is at the internal auditory meatus or in the middle ear or at the geniculate ganglion the taste fibres are involved and taste is lost on the anterior two thirds of the tongue on the affected side

1 BELL S PALSY

Synonym —Common facial paralysis

Definition —Paralysis of the facial nerve coming on acutely and not associated with any other lesion

Ætiology —The pathogenesis of Bell s palsy has been the subject of considerable discussion but the work of Ballance and Duel confirmed that the nerve was compressed just within the styloid foramen Inflammation of the fibrous tissue around the nerve outside the facial canal is believed to cause swelling of the nerve with the result that the nerve strangulates itself at the foramen The inflammation of its fibrous sheath may have spread some millimetres up the facial canal before this occurs because Ballance and Duel found scarring and contraction of the sheath extending for 4 or 5 mm when the lower portion of the canal was opened up As the chorda tympani nerve leaves the facial canal 2 to 3 mm above its termination the lesion may extend up far enough to involve it

Bell s palsy may occur at any age but is commonest between 20 and 50 The sexes are equally affected and no predisposing factors are known

Symptoms —The onset is usually rapid and sometimes even sudden Pain of a neuralgic character below the ear behind the mastoid process or referred to the occipital region is common but it does not last more than a few days and sometimes pain is entirely absent. On deep pressure upon the styloid region behind the ramus of the jaw on both sides one can almost always elicit the fact that there is tenderness on the paralysed side and sometimes obvious swelling of this region may be felt The first sign of the facial paralysis is that the patient feels the face to be stiff when he attempts to move it Subsequently the paralysis appears rapidly and the face is drawn over to the opposite side The paralysed side is motionless according to the degree and distribution of the paralysis if incomplete and if complete is expressionless The eye cannot be closed and there is epiphora from paralysis of the tensor tarsi The paralysis at the corner of the mouth causes difficulty in articulation and escape of fluids on drinking but the patient soon learns to overcome these disabilities When the paralysis is partial it is nearly always the lower part of the face which is the most affected The facial muscles soon become hyperexcitable to mechanical stimuli In nearly all the severe cases there is loss of taste over the anterior part of the tongue

There is never any pain in the distribution of the facial nerve After a time which may vary from a few days to 2 years the paralysis begins to recover and invariably this recovery appears in the upper facial region first

In not a few cases however recovery remains imperfect and a degree of contracture occurs in the paralysed muscles with the result that the corner of the mouth ceases to droop and at rest the asymmetry of the face is not marked though with movement the limited action of the affected side is apparent

In rare instances Bell s palsy occurs more than once in the same individual and not necessarily on the same side It is conceivable that the true Bell s palsy may sometimes be bilateral but when bilateral facial paralysis occurs infective polyneuritis should be suspected and other signs sought for

Diagnosis —Care in diagnosis is most important since there are many causes of facial paralysis and few of them have as favourable a prognosis as Bell s palsy Facial paralysis from caries of the temporal bone rarely makes any recovery and it is usually associated with partial deafness A general examination of the nervous system should be made in every case and if any other abnormal signs are found the facial paralysis is most probably due to some cause other than Bell s palsy Again cases of facial paralysis that are slow in their onset are not cases of Bell s palsy

Facial paralysis from herpes of the geniculate ganglion —Among the not infrequent

causes of facial palsy must be numbered geniculate herpes to which attention was first drawn by Ramsay Hunt The herpetic vesicles preceded by local pain, appear in the external auditory meatus and adjacent parts of the pinna (and sometimes also just behind the pinna) and on the soft palate and anterior pillar of the fauces When the innervation of the last named derives fibres from the geniculate ganglion the clinical picture of geniculate herpes is apt to be a misleading one if it be not thought of The patient complains of pain in the ear, and in the throat on the same side As the eruption develops the fauces on the affected side are red and injected and several small ulcers (ruptured vesicles) may be seen At the same time the vesicles appear in the ear rupture and give off a watery discharge which may be mistaken for otorrhœa The pinna may then swell very considerably After some days during which the patient may feel ill and be feverish (temperature 100° to 103° F) facial paralysis develops and usually becomes complete within 12 hours Tinnitus vertigo and a varying degree of deafness are usually present In milder cases there may be only initial pain in the pinna and the appearance of herpetic vesicles on the pinna without much swelling It is in the severe cases that an erroneous diagnosis of *middle ear disease with otorrhœa may be made and hazardous and unnecessary steps* be taken to deal with this According to Ramsay Hunt facial palsy always follows geniculate herpes and undoubtedly many cases of this kind, where the herpetic eruption is minimal escape accurate diagnosis

Course and Prognosis—Recovery of Bell's palsy can in general be promised with some reservation as to its completeness particularly in elderly subjects The date of recovery is often difficult to forecast. If at the end of a week after the onset there is the slightest trace of any voluntary power in the orbicularis palpebrarum which is the ultimum moriens of the facial muscles, or if any trace of faradic excitability to bearable stimuli remains then it may be confidently said that recovery will be complete and rapid within 3 months and that there will be no contracture Cases in which no complete paralysis occurs in any region of the face usually recover in a fortnight In complete cases with complete reaction of degeneration in the muscles it is difficult to say when recovery will occur or when the effect of contracture will be at an end Cases which show no loss of taste and therefore in which there is no great extension of the inflammatory process up the *facial canal*, usually recover rapidly

In cases with imperfect recovery either continuous spasm or intermittent twitching of the partly recovered muscles may occur and may persist indefinitely causing disfigurement and discomfort

Treatment—In the acute stage salicylates and iodides may be given internally and warmth or a counter irritant such as tincture of iodine applied behind the angle of the jaw The patient should stay in the house for the first week and gentle massage may be given to the paralysed side of the face When paralysis seems to be complete undue stretching of the paralysed muscles may be minimised by splinting' the face for this purpose a silver wire rubber covered where it turns round the lip may be bent so as to hook round the lip at one end and over the ear at the other so that the mouth is kept symmetrical during facial movements Gentle massage should also be continued

It is customary to give galvanic stimulation to the paralysed muscles but if it is employed *the onset of contracture must be watched for and* the applications stopped at the first sign of it

Ballance and Duel recommended that at an early stage the lower portion of the facial canal should be opened up and the nerve thus decompressed This operation should certainly be considered if by the end of a month no sign of recovery has shown itself either to clinical examination or to electrical testing

When complete paralysis persists after a year no recovery can be expected and the disfigurement can be relieved by one of the varieties of sling operation

2 PERIPHERAL FACIAL SPASM

Synonym —Facial Hemispasm

Definition —A unilateral malady of the facial nerve in which intermitting spasm of the facial muscles occurs exactly like that caused by faradism of the facial trunk Rarely it is associated with a slowly oncoming facial paralysis and may follow a facial paralysis due to injury

Ætiology —This malady occurs in adults and the onset is usually insidious and without known cause It is most often seen in middle aged women

Symptoms —It commences with twitching of some part of the facial musculature which occurs at first at rare intervals and subsequently becomes more and more frequent so as in some cases to be almost continuous Commencing locally usually around the eye it tends to spread so as to involve the whole face in a sudden and hideous contortion The attacks of peripheral facial spasm may at first glance resemble a Jacksonian fit of the face The spasms may be so severe and continuous as to keep the eye closed for long periods together and to interfere greatly with the work and enjoyment of life The malady is associated with no other symptoms Cases exist in all degrees of severity from the mildest in which an occasional flicker of the face occurs to the most severe and incapacitating and unsightly malady

Treatment —In severe cases the only remedy which affords relief is division and alcoholic injection of some of the branches of the facial nerve in the pes anserinus or possibly of the whole of the nerve at the stylo mastoid foramen or as it crosses the ramus of the jaw The resulting paralysis and disfigurement if a large part of the nerve is divided will call for a cosmetic operation As long as the spasm is mild, such treatment is obviously worse than the disease No other treatment has any effect on the spasm but sedatives may enable the patient to bear it with less distress

THE AUDITORY AND VESTIBULAR NERVES

The eighth nerve consists of two groups of fibres different in their functions and in their origins and terminations one group arising in the cochlea and terminating in the cochlear nuclei in the pons is called the auditory or cochlear nerve the other arising from the labyrinth and ending mostly in the vestibular nuclei is called the vestibular nerve

Lesions of the auditory nerve (as well as diseases of the cochlea) give rise to two symptoms nerve deafness and tinnitus

Nerve deafness is distinguished from deafness due to middle ear disease by the fact that hearing is diminished or lost whether the sound be conveyed by air conduction or by bone conduction whereas in middle ear deafness the hearing by bone conduction is increased Weber s test consists in the application of the base of a vibrating tuning fork to the middle of the forehead the patient being asked in which ear the sound seems the louder with middle ear deafness the sound is heard better on the affected side while with inner ear or nerve deafness the opposite is the case or the patient does not appreciate any difference between the two sides For Rinne s test the fork is applied first to the mastoid process and when the patient ceases to hear *it is held at the external auditory meatus in nerve deafness the sound may be heard* by air conduction after it has become too feeble to be heard by bone conduction while in middle ear deafness the opposite obtains As a symptom of nervous disease nerve deafness is met with in cases of tumour of the eighth nerve following epidemic meningitis in syphilis of the nervous system especially *congenital syphilis* and in disease of the lateral region of the medulla

Tinnitus is a subjective sensation of noise in the ears or in the head It seems to

be due to disease of the cochlea or auditory nerve of a slow degenerative nature and though at first intermittent it usually becomes continuous before long It may also be produced temporarily by certain drugs of which quinine and salicylates are the commonest

The sounds commence faintly and at first may be perceived only in stillness and silence at night and later become louder and more persistent, and are often absolutely continuous The noise complained of may be high pitched or low pitched a piercing whistle or a hiss or even a rumble in some cases it is more elaborated and is described as like machinery or again ' bell like

In the course of time the hearing becomes impaired and in some patients vertigo occurs and may be associated with periods of aggravation of the tinnitus Medical treatment produces little benefit but sedatives such as phenobarbitone, may enab' the patient to tolerate the noise better Division of the eighth nerve often cures the tinnitus, but the patient must be warned both that it may fail to do so and that in any case the operation will produce complete deafness on the side on which the operation is performed

The most prominent symptom which results from lesions of the vestibular nerve (as well as from disorders of the labyrinth) is *vertigo* The word by derivation means 'a turning , and with vertigo of labyrinthine and vestibular nerve origin there is always a sense of rotation either of the surroundings or of the patient himself the room may seem to rotate about a vertical or a horizontal axis and there is often a disorder of projection so that when the patient falls it seems to him that the floor has come up to strike his head

It must be noted that the vast majority of patients who complain of giddiness or dizziness do not suffer from true vertigo Nearly all those who suffer from functional nervous disturbances complain of what they call dizziness, by which they mean a momentary sensation of unsteadiness objectively such a patient is not unsteady and this sensation never causes him to fall Patients suffering from generalised cerebral arteriosclerosis complain of a similar sensation as also do those who are suffering from the after effects of head injuries

With true vertigo unless it be minimal nystagmus is always present while the vertigo is going on Usually the nystagmus is seen with deviation of the eyes towards the side of the lesion but with irritative lesions of the labyrinth *e g* for a day or two after operations on the ear and with labyrinthitis the nystagmus is towards the opposite side

Tests for vestibular lesions—1 Barany s caloric test is made by irrigating the external auditory meatus with either hot or cold water or air With an intact vestibular mechanism this causes irritation of the vestibular apparatus with the appearance of nystagmus on lateral deviation of the eyes When the vestibular mechanism is impaired this test fails relatively or completely

2 If the patient be rotated either by placing him in a special rotating chair or by turning him round several times in the standing position lateral conjugate deviation of the eyes immediately after the rotation will show nystagmus in the opposite direction to the rotation if the labyrinth on that side is intact It will not appear if the functional activity of the vestibular mechanism is deficient

RECURRENT VERTIGO

The causes of recurrent vertigo are various It is necessary in every instance to make sure that there are no indications of disease of the cerebellum brain stem or cerebello pontine angle but in the great majority of cases the symptom arises from disease of the labyrinth or vestibular nerve and the following conditions have been identified (1) Meniere s disease (2) vestibular neuronitis (Dix and Hallpike) (3) positional vertigo

1 MÉNIÈRE S DISEASE

Definition —A malady in which paroxysmal attacks of labyrinthine vertigo occur at irregular intervals associated with tinnitus and progressive deafness and due to disease of the labyrinth of a chronic nature

Ætiology —Ménière s original hypothesis was that hæmorrhage into the labyrinth was the responsible factor but this is inherently improbable and lacks pathological support According to Hallpike the essential lesion is a gross distension of the endo lymph system together with degenerative changes in Corti s organ and the presence of albuminoid coagula throughout the endolymph spaces He regards these changes as incompatible with an infective origin and as probably primarily degenerative in nature

The precipitating causes of the attacks are unknown and in the absence of precise knowledge disturbances of fluid balance allergy and migraine have all been incrimin ated in some instances the attacks are associated with diarrhœa

Symptoms —The majority of cases are much milder than those described by Menière and the symptoms may be subject to long remissions

In the severe cases of the classical type the attacks set in suddenly with a buzzing noise in the ears followed immediately by intense vertigo both subjective and objec tive The vertigo may be so severe that the patient feels he is hurled to the ground He often falls as if shot but sometimes he has time to assume the sitting or lying position before the vertigo reaches its height Consciousness may rarely be impaired for a few moments Spontaneous nystagmus occurs to the side of the lesion and unilateral cerebellar signs on the side of the lesion The patient becomes nauseated and often vomits repeatedly The skin is pale and covered with a clammy sweat The patient lies perfectly still and in terror lest the least movement should bring on more vertigo The duration of the attack is usually between 15 minutes and an hour but the patient may take several hours to recover completely Sometimes the attacks are excited by sudden movement such as coughing or sneezing but they are usually without any such antecedent They may occur during sleep and wake the patient In the milder cases the vertigo is not infrequently present when the patient wakens in the morning and becomes apparent to him as soon as he moves It is not spon taneous but is brought on by movements of the head and it is also influenced by the posture of the head being worse when the affected ear is on the pillow The vertigo passes off within half an hour or an hour or two

Menière s disease is characterised by a slow onset of nerve deafness and by the time the first attack of vertigo occurs an impairment of hearing and some tinnitus are usually present If the disease is persistent there is a gradual deterioration both of vestibular and of auditory function in the affected ear and in some cases the laby rinth becomes defunct and the attacks cease

Diagnosis — This presents no peculiar difficulty for the symptoms are highly characteristic and although variable in degree are usually quite definite in the first attack The rapid disappearance of the vertigo is striking Vertiginous attacks from all other causes must be excluded In acute cerebellar lesions (including thrombosis of the posterior inferior cerebellar artery) the symptoms are very like those of laby rinthine vertigo but they are not transitory in a few hours A careful search of the nervous system for signs of organic nervous disease should in every case prevent any mistake Vertiginous attacks due to epilepsy rarely cause difficulty in the differential diagnosis because the loss of consciousness and probably the convulsive and other features of the epileptic attack are apparent

Prognosis —Most cases recover perfectly with slight impairment of hearing or have long periods of remission Some cases however go from bad to worse in spite of treatment and progressive deafness ensues with eventual disappearance of the attacks

be due to disease of the cochlea or auditory nerve of a slow degenerative nature and though at first intermittent it usually becomes continuous before long It may also be produced temporarily by certain drugs of which quinine and salicylates are the commonest

The sounds commence faintly and at first may be perceived only in stillness and silence at night and later become louder and more persistent and are often absolutely continuous The noise complained of may be high pitched or low pitched a piercing whistle or a hiss or even a rumble, in some cases it is more elaborated and is described as like machinery' or again 'bell like

In the course of time the hearing becomes impaired and in some patients vertigo occurs and may be associated with periods of aggravation of the tinnitus Medical treatment produces little benefit but sedatives such as phenobarbitone may enable the patient to tolerate the noise better Division of the eighth nerve often cures the tinnitus but the patient must be warned both that it may fail to do so and that in any case the operation will produce complete deafness on the side on which the operation is performed

The most prominent symptom which results from lesions of the vestibular nerve (as well as from disorders of the labyrinth) is *vertigo* The word by derivation means a turning , and with vertigo of labyrinthine and vestibular nerve origin there is always a sense of rotation either of the surroundings or of the patient himself the room may seem to rotate about a vertical or a horizontal axis and there is often a disorder of projection so that when the patient falls it seems to him that the floor has come up to strike his head

It must be noted that the vast majority of patients who complain of giddiness or dizziness do not suffer from true vertigo Nearly all those who suffer from functional nervous disturbances complain of what they call dizziness by which they mean a momentary sensation of unsteadiness objectively such a patient is not unsteady and this sensation never causes him to fall Patients suffering from generalised cerebral arteriosclerosis complain of a similar sensation as also do those who are suffering from the after effects of head injuries

With true vertigo unless it be minimal nystagmus is always present while the vertigo is going on Usually the nystagmus is seen with deviation of the eyes towards the side of the lesion but with irritative lesions of the labyrinth *e g* for a day or two after operations on the ear and with labyrinthitis the nystagmus is towards the opposite side

Tests for vestibular lesions —1 Barany s caloric test is made by irrigating the external auditory meatus with either hot or cold water or air With an intact vestibular mechanism this causes irritation of the vestibular apparatus with the appearance of nystagmus on lateral deviation of the eyes When the vestibular mechanism is impaired this test fails relatively or completely

2 If the patient be rotated either by placing him in a special rotating chair or by turning him round several times in the standing position lateral conjugate deviation of the eyes immediately after the rotation will show nystagmus in the opposite direction to the rotation if the labyrinth on that side is intact It will not appear if the functional activity of the vestibular mechanism is deficient

RECURRENT VERTIGO

The causes of recurrent vertigo are various It is necessary in every instance to make sure that there are no indications of disease of the cerebellum brain stem or cerebello pontine angle but in the great majority of cases the symptom arises from disease of the labyrinth or vestibular nerve and the following conditions have been identified (1) Meniere s disease (2) vestibular neuronitis (Dix and Hallpike) (3) positional vertigo

Symptoms—When fully developed the malady consists in paroxysms of shooting pain of great severity in the region of the throat and ear The exciting stimulus is commonly the act of swallowing But just as in trigeminal neuralgia the pain may at first be confined to a single branch of this nerve so in glossopharyngeal neuralgia the pain may for long be confined to the tympanic branch the pain being felt deep in the ear This pain does not spread to the pinna In other cases pain in the faucial region predominates the pharyngeal branches being affected As in trigeminal neuralgia the patient may enjoy long intervals of freedom from pain During a paroxysm the patient screws up his face and may hold his head in his hand as does the subject of trigeminal neuralgia

Diagnosis—The presence of neuralgic pain of great severity provoked by the act of swallowing and in its general characters and behaviour resembling the very familiar and characteristic paroxysms of trigeminal neuralgia but different from these in its restriction to the ear and throat occurring also in the absence of objective signs of a lesion of the cranial nerves these together are the features which make a diagnosis of glossopharyngeal neuralgia possible and easy

Treatment—In the early attacks the same forms of medication as are used in trigeminal neuralgia may be employed If the pain does not respond to these then surgical measures are called for and the operation usually performed is avulsion of the nerve high in the neck

THE TENTH OR VAGUS NERVE

This is a mixed nerve The motor fibres supply the voluntary muscles of the soft palate (except the tensor palati) pharynx and larynx in conjunction with the accessory fibres and also the non striped muscles of the respiratory and alimentary tracts

The sensory fibres of the vagus supply the respiratory tract the pharynx and œsophagus Its visceral fibres supply the lungs heart and abdominal viscera No sensibility seems to be supplied to the abdominal viscera by this nerve since with division of the spinal cord above the offshoot of the splanchnic nerves all sensibility in the abdomen is lost

LESIONS OF THE VAGUS

The important signs of lesion of this nerve and its nuclei are pharyngeal and laryngeal paralysis and loss of sensibility Symptoms indicative of lesions of its complicated and mysterious visceral supply are neither well marked nor well understood and in unilateral lesions seem to be entirely absent they are therefore not considered

Lesions of the vagus in the medulla are common Syringomyelia when affecting that region usually involves the nucleus ambiguus causing unilateral palsy of palate pharynx and larynx Thrombosis of the posterior inferior cerebellar artery which supplies that region of the medulla containing the nucleus ambiguus is likely to produce vagus paralysis of the same side Progressive muscular atrophy in the form of progressive bulbar paralysis may affect its cells Lesions of the nerve roots often occur from tumours of the lateral region of the medulla, and growths outside the medulla arising from nerve roots or meninges and here the lesion of the vagus roots is associated usually with those of the glossopharyngeal spinal accessory and hypoglossal In the neck penetrating wounds and growths may implicate the nerve and in the thorax tumours particularly aneurysms and new growths are apt to cause paralysis of the muscles supplied by its recurrent branch

Unilateral pharyngeal paralysis—This is characteristic of all unilateral lesions of

Treatment—Sedatives have a pronounced palliative effect The most commonly used drug is phenobarbitone, and doses of gr ½ taken three or four times daily usually bring about prompt amelioration Bromides in doses of gr 10 to 15 three times a day are equally serviceable and Gowers advocated the use of sodium salicylate or aspirin Other measures include a salt free diet, careful regulation of the bowel to prevent diarrhœa and the use of anti histamine drugs Dimenhydrinate (Dramamine) is believed by some to have a selective action as a sedative on the labyrinth

When medical treatment fails surgical measures may give relief the principal operations employed being division of the vestibular nerve partial removal of the membranous labyrinth and total destruction of the labyrinth of one side

2 VESTIBULAR NEURONITIS

In this condition the cause of the vertigo is believed not to be in the labyrinth but in the neurones of the vestibular nerve There is no disturbance of hearing In a large proportion of cases there is an associated infection in the nasal sinuses or elsewhere or the onset is associated with some febrile illness The disorder affects chiefly patients in the age group 30 to 50 without preference for sex

The attacks of vertigo are similar to those of Menière s disease but are in general less severe

Treatment consists in the administration of phenobarbitone as for Menière's disease and the removal of any local or general infection which can be discovered With these measures the liability to vertigo usually passes off in the course of a few months

3 POSITIONAL VERTIGO (POSITIONAL NYSTAGMUS)

In this variety the vertigo always occurs when the head is put in a particular position, and in most instances the exciting position is with the head back and somewhat tilted to one side Many of the cases are subsequent to head injury

The condition can usually be identified by the patient s complaint that he becomes dizzy when he turns his head (face) upwards, but specialised tests are necessary to confirm the diagnosis

Treatment consists as before in the use of phenobarbitone and in most cases the symptoms pass off completely in 3 to 12 months

THE NINTH OR GLOSSOPHARYNGEAL NERVE

Lesions of this nerve involve loss of taste over the posterior one third of the tongue with some unilateral paresis of the pharynx It is rarely involved alone in association with the other nerves taking origin in the neighbourhood it may be affected by tumours of the lateral region of the medulla and by syringomyelia

GLOSSOPHARYNGEAL NEURALGIA

Definition—A comparatively rare form of neuralgia within the distribution of the glossopharyngeal nerve It is strictly comparable with trigeminal neuralgia in the quality and severity of the pain its paroxysmal incidence the remissions in its course its provocation by special stimuli and finally by the absence of any discoverable lesion in or loss of function of the nerve

Ætiology—Nothing is known of its ætiology It is most frequently seen in middle aged or elderly males A symptomatic neuralgia of the same distribution is occasionally found in cases of carcinoma of the tongue in which the growth invades the faucial region

of the weakness the shoulder falls a little the scapula moves slightly laterally and by the unopposed action of the rhomboids and levator anguli scapulæ it is rotated the lower angle moving medially

THE TWELFTH OR HYPOGLOSSAL NERVE

The hypoglossal nerve supplies all the muscles of the tongue both intrinsic and extrinsic.

A lesion of one hypoglossal nucleus in the medulla gives rise to fibrillation and eventual atrophic paralysis of one half of the tongue When the hypoglossal nerve is divided the fibrillation is usually not apparent but the atrophy occurs more quickly and there is a loss of faradic excitability In either event the tongue becomes sickle shaped with the concavity on the paralysed side There is little impairment of movement within the mouth and no defect of articulation but the tongue turns to the paralysed side when protruded Such hemiatrophy of the tongue occurs in syringo bulbia and in syphilitic conditions tumours of the lateral region of the medulla and just lateral to it are rarer causes of it The hypoglossal nerve may be severed as a result of wounds or operations in the neck

Atrophic paralysis of the whole tongue occurs when both hypoglossal nuclei are affected and is commonly seen in progressive bulbar paralysis Protrusion of the tongue is impossible and articulation is greatly impaired but this may be partly due to other paralyses which are usually associated

Upper motor neurone paralysis of the tongue is not uncommon A patient suffering from motor aphasia is commonly unable to protrude his tongue and in bilateral hemiplegia and the condition known as pseudo-bulbar paralysis, the tongue is in a state of spastic paralysis neighbouring parts are similarly affected and well-marked dysarthria and dysphagia are frequent The tongue appears contracted but there is no real wasting and no loss of electrical excitability

THE SIGNS OF LOCAL LESIONS WITHIN THE SKULL AND BRAIN

In this chapter we must be content with a brief consideration of the signs and symptoms upon which we depend for the localisation of cerebral lesions We may take first the various regions of the brain and secondly as we have to deal not only with lesions within the brain but also with lesions within the skull that may be out side the brain itself we will consider the symptomatology peculiar to lesions in the three cranial fossæ

THE CEREBRAL HEMISPHERES

GENERAL LATERALISING SIGNS

A lesion within or involving one cerebral hemisphere may reveal by the signs it produces whether it is right or left sided without affording further evidence of its localisation Such signs are unilateral loss or diminution of the abdominal reflexes unilateral accentuation of the tendon reflexes an extensor response or just perceptible unilateral paresis of movement of the lower part of the face Fits starting unilaterally, or with turning of the head and eyes to one side may be of similar significance

the vagus high up It is recognised by the low lying motionless palate and the loss of sensibility of one side of the pharynx with loss of the pharyngeal reflex on that side There is no impairment whatever of deglutition When the soft palate is elevated as in saying Ah! it is pulled over to the sound side.

Bilateral pharyngeal paralysis—This results from nuclear lesions of the nucleus ambiguus on both sides and is also common in diphtheria polyneuritis myasthenia gravis and progressive muscular atrophy The whole palate is low and paretic or paralysed the voice is nasal there is nasal regurgitation of liquids, the cheeks cannot be forcibly blown out and there is difficulty in pronouncing final 'k and g, the words 'kick and egg' becoming *kich* and '*enck*

Total unilateral laryngeal paralysis—Since the superior laryngeal nerve which supplies the crico thyroid muscle (the chief tensor and adductor of the vocal cords) is given off high in the neck from the ganglion of the trunk of the vagus it follows that total paralysis of the larynx on one side can only result from a lesion of the vagus between the ganglion of the trunk and the nucleus ambiguus in the medulla The vocal cord on the paralysed side becomes motionless in the cadaveric position—that is, midway between the abduction and adduction The larynx is insensitive on the same side There is some loss of tone of voice but no stridor.

Unilateral abductor paralysis or recurrent laryngeal paralysis—This occurs from all lesions of the trunk of the vagus below the ganglion of the trunk and from lesions of the recurrent laryngeal branch The vocal cord on the side of paralysis lies close to the mid line it fails to abduct when the patient takes a deep breath there is no change of voice but there may be slight stridor on inspiration The sensibility of the larynx is not affected

Bilateral abductor paralysis—This condition is occasionally seen as a complication of thyroidectomy and in malignant disease of the thyroid gland It occurs also in bilateral lesions of the recurrent laryngeal nerves in the thorax which may occur from aneurysm and new growths It is the most dangerous form of laryngeal palsy as the vocal cords cannot be abducted and they tend to suck together during inspiration for this reason bilateral abductor paralysis may cause death from asphyxia *or necessitate tracheotomy*

THE ELEVENTH OR SPINAL ACCESSORY NERVE

This nerve may be caught with the vagus by lateral lesions outside the medulla or by lesions in the region of the jugular foramen but it is more often damaged by injuries to the neck and by operations for the removal of cervical glands The spinal accessory nerve as it crosses the posterior triangle of the neck is very liable to injury either from blows or from sudden strains and most of the isolated trapezius palsies are due to local neuritis of the nerve trunk so arising

When the sternomastoid is paralysed there is neither complaint by *the patient* of weakness *nor deformity nor peculiar attitude of the neck* other muscles compensating for its paralysis The muscle does not harden when the head is turned to the side opposite to the paralysis and its reaction to faradism is diminished or lost

Paralysis of the trapezius on the other hand causes great disability in raising the arm above the horizontal level of the shoulder and also difficulty in shrugging the shoulder or approximating the scapula to the middle line behind and therefore also in carrying the extended arm backwards But the only part of the trapezius that is completely paralysed by disease of the spinal accessory nerve is the highest portion Instead of its normal nearly straight contour the neck presents on the affected side a concave curve and the difference between the two sides is brought out more strongly by a deep inspiration The other parts of the trapezius are weakened but not paralysed since they receive additional innervation from the cervical nerves In consequence

In such cases the patient becomes completely apathetic silent and immobile lying with open eyes, but displaying no initiative of any kind

SYNDROMES OF THE CENTRAL REGION (REGION OF THE MOTOR CORTEX ')

Hemiplegia is the characteristic symptom of a paralytic lesion in this portion of the hemisphere and the Jacksonian fit that of an irritative lesion

The Jacksonian, or focal fit most commonly originates in the face, thumb or big toe and thence spreads with varying rapidity until much or all of the corresponding side of the body is affected It may then become generalised Consciousness is commonly preserved in attacks which remain unilateral Such a fit may be accompanied by conjugate deviation of the head and eyes away from the side of the lesion and may be followed by a transient hemiparesis or in the case of a tumour by a progressive and permanent hemiplegia The hemiparesis resulting from a destructive lesion near the surface will affect face arm or leg predominantly according to the site of the lesion The more deeply this extends into the underlying white matter the more will the weakness affect the whole half body since the pyramidal fibres converge from the cortex towards the capsule Disturbances of cortical sensibility corresponding in distribution to the motor defect are not infrequent and result from simultaneous involvement of the neighbouring post central convolution

PARIETAL LOBES

Irritative lesions in this area may give rise to focal fits heralded by subjunctive sensory disturbances on the opposite side These are usually described as consisting of numbness tingling or pins and needles and may spread in an orderly manner to other parts of the affected side of the body in the same way as the muscular spasm in discharging lesions of the motor cortex Destructive lesions in this neighbourhood may be marked by a characteristic series of sensory disturbances These include defective localisation of tactile stimuli defective appreciation of two simultaneous contacts (Weber s compass test) defective appreciation of three dimensional space (i e size and form) There is in addition defective power of differentiating minor differences in intensity of painful or thermal stimuli and a ready fatigue of sensory functions The simple recognition of such stimuli may be relatively intact It will be seen that the defects in spatial discrimination which result from these modes of sensory loss lead to that inability to recognise and identify objects held in the hand or to describe their size shape or texture which is known as astereognosis The appreciation of movement and of position is apt to be faulty and some ataxy commonly results Disturbances of attention may also occur on the contralateral side of the body together with failure of spatial orientation and of recognition of the body image In left sided lesions there may in addition be disorders of the visual speech function resulting in dyslexia agraphia and acalculia Trophic changes particularly decrease in size of the muscles may be seen in the periphery of the limbs and this may be so marked as to amount to true muscular wasting

OCCIPITAL LOBES

Lesions of the cuneus and region of the calcarine fissure on the mesial aspect of the occipital lobe result in hemianopia of the opposite field but central vision escapes Gordon Holmes showed that if the lesion is limited above the calcarine fissure a quadrantic hemianopia of the lower field results and if the lesion is below the calcarine fissure the quadrantic defect resulting is of the upper field Since central vision is represented at each occipital pole a lesion of either pole causes contralateral,

THE FRONTAL LOBES

These consist of the portions of the hemispheres anterior to the coronal sulci (*fissures of Rolando*) and thus include the ascending frontal convolutions and the portions of the hemispheres anterior to them (*the 'prefrontal' areas*) The lesions to be met with in the prefrontal areas include tumour abscess and thrombosis of the anterior cerebral artery the last named being comparatively rare

The syndrome of the anterior cerebral artery consists of a spastic weakness of the opposite lower limb, especially in its distal part with the appropriate changes in its reflexes Sometimes there is slight weakness of the corresponding arm which may be associated with forced groping and grasping in the arm on one or both sides The face is seldom affected Apraxia of the left arm has been described and there may be some drowsiness and mental confusion

The syndrome of frontal lobe tumour.—The area of the frontal lobes anterior to the ascending frontal convolutions (the prefrontal areas) comprises a considerable portion of the cerebrum and is frequently the site of tumour formation The symptoms produced vary greatly with the rapidity of growth of the tumour and with other factors imperfectly understood As a rule an early if not the initial symptom, is a change in the patient s mental state He becomes apathetic and lacking in initiative The association and flow of ideas tend to fail He sits about idly, lacks attention and becomes indifferent to cleanliness and other aspects of personal behaviour He is apt to permit the unhindered passage of urine and even of fæces and to be totally insensitive to the embarrassments such conduct normally involves This form of incontinence is in fact a diagnostic symptom of great value in frontal lobe tumours Rarely, the patient develops an abnormal facetiousness and euphoria—the so called 'Witzelsucht' These early symptoms may gradually give place to a profound dementia

Movement is often disordered by the development of apraxia and sometimes by that of forced groping and grasping which when unilateral is a useful sign of frontal lobe involvement When bilateral it is of less localising significance and may be met with in diffuse degenerative or neoplastic lesions of the hemispheres and in cases of severe internal hydrocephalus Such grasping and groping has been shown to consist of two components (i) Volitional grasping movements made by the conscious patient when some object is felt by him in his palm or is seen by him to approach his hand These movements wane and cease when consciousness is failing or when attention is defective (ii) A true tonic reflex grasp of any object held in the hand if this object be pulled away in such a manner as to put the flexors of the fingers on the stretch The flexors tighten as the pull is maintained and their contraction may attain great force such indeed that sometimes the patient can be pulled out of bed by this involuntary grasp which he is unable voluntarily to relax This reflex may persist even after consciousness is lost but is abolished by injection of novocaine into the appropriate afferent nerves Fits are a common feature of frontal tumours and may be generalised from their onset or start with turning of the head and eyes to the opposite side Attacks of petit mal are not uncommon If the orbital lobule be involved there may be unilateral anosmia or direct pressure on the optic nerve causing unilateral failure of vision associated with primary optic atrophy This when combined with papillœdema in the opposite eye has been described as Foster Kennedy s syndrome These symptoms will be further considered in connection with the syndrome of the anterior cranial fossa

As the tumour expands it is likely to encroach upon the projection pathway from the motor cortex with a resulting contralateral hemiparesis and when left sided it is commonly associated with a predominantly executive disturbance of speech Tumours in the medial portions of the frontal lobes may come to involve the corpus callosum and frequently spread through this structure to the opposite hemisphere

In such cases the patient becomes completely apathetic silent and immobile, lying with open eyes but displaying no initiative of any kind

SYNDROMES OF THE CENTRAL REGION (REGION OF THE 'MOTOR CORTEX')

Hemiplegia is the characteristic symptom of a paralytic lesion in this portion of the hemisphere and the Jacksonian fit that of an irritative lesion

The Jacksonian, or focal fit most commonly originates in the face, thumb or big toe and thence spreads with varying rapidity until much or all of the corresponding side of the body is affected It may then become generalised Consciousness is commonly preserved in attacks which remain unilateral Such a fit may be accompanied by conjugate deviation of the head and eyes away from the side of the lesion and may be followed by a transient hemiparesis or in the case of a tumour by a progressive and permanent hemiplegia The hemiparesis resulting from a destructive lesion near the surface will affect face arm or leg predominantly according to the site of the lesion The more deeply this extends into the underlying white matter the more will the weakness affect the whole half body since the pyramidal fibres converge from the cortex towards the capsule Disturbances of cortical sensibility corresponding in distribution to the motor defect are not infrequent and result from simultaneous involvement of the neighbouring post central convolution

PARIETAL LOBES

Irritative lesions in this area may give rise to focal fits heralded by subjunctive sensory disturbances on the opposite side These are usually described as consisting of numbness tingling or pins and needles and may spread in an orderly manner to other parts of the affected side of the body in the same way as the mu cular spasm in discharging lesions of the motor cortex Destructive lesions in this neighbourhood may be marked by a characteristic series of sensory disturbances These include defective localisation of tactile stimuli defective appreciation of two simultaneous contacts (Weber s compass test) defective appreciation of three dimensional space (i e size and form) There is in addition defective power of differentiating minor differences in intensity of painful or thermal stimuli and a ready fatigue of sensory functions The simple recognition of such stimuli may be relatively intact It will be seen that the defects in spatial discrimination which result from these modes of sensory loss lead to that inability to recognise and identify objects held in the hand, or to describe their size shape or texture which is known as astereognosis The appreciation of movement and of position is apt to be faulty and some ataxy commonly results Disturbances of attention may also occur on the contralateral side of the body together with failure of spatial orientation and of recognition of the body image In left sided lesions there may in addition be disorders of the visual speech function, resulting in dyslexia agraphia and acalculia Trophic changes particularly decrease in size of the muscles may be seen in the periphery of the limbs and this may be so marked as to amount to true muscular wasting

OCCIPITAL LOBES

Lesions of the cuneus and region of the calcarine fissure on the mesial aspect of the occipital lobe result in hemianopia of the opposite field but central vision escapes Gordon Holmes showed that if the lesion is limited above the calcarine fissure a quadrantic hemianopia of the lower field results and if the le ion is below the calcarine fissure the quadrantic defect resulting is of the upper field Since central vision is represented at each occipital pole a lesion of either pole causes contralateral

central homonymous hemianopic scotomata vision in the periphery of the field remaining intact Similarly a bilateral lesion involving both occipital poles will result in bilateral central scotomata *and a bilateral lesion of the calcarine region will produce* blindness of both peripheral fields, central vision remaining intact If the lesion extends deeply into the occipital lobe so as completely to sever the optic radiation to the occipital cortex complete hemianopia affecting both the peripheral and central parts of the visual fields will result The hemianopias resulting from a lesion of the occipital lobes have been distinguished from those due to lesions of the optic tracts by the fact that in the former the pupils react to light thrown on to the blind part of the field (Wernicke s hemianopic pupil phenomenon) To be of practical value this test needs to be made with a very narrow pencil of parallel rays to avoid the effects of dispersal of light within the eye

On the outer surface of the occipital lobe a lesion on the left side may sever the connections between the visual centres and the speech centres and so produce word blindness Bilateral lesions in this region may be associated with visual disorientation

Jacksonian attacks are often of great value in the localisation of occipital lobe lesions When the lesion is situated posteriorly these take the form of undifferentiated visual *hallucinations* such as flashes of light or coloured figures *When the lesion* is situated more anteriorly at the junction of the occipital and temporal lobes the visual hallucinations may take the more elaborate form of visions of people animals or places In either case the hallucinations may be accompanied or followed by a transient hemianopia

TEMPORAL LOBES

The considerable portion of the cortex comprised by the temporal lobes includes the cortical representation of the functions of smell taste and hearing and on the left side in normal right handed persons the function of speech

The uncinate and hippocampal regions of these lobes are the cortical seats for taste and smell and the localising symptoms which are rarely absent when lesions in these regions exist are Jacksonian attacks taking the form of hallucinations of taste and smell nearly always of an unpleasant character The hallucination is often accompanied or immediately followed by a dreamy state in which the patient *may* experience a feeling of strangeness or of intense familiarity or a panoramic recall of events of his past life This tate of altered consciousness may be accompanied by smacking of the lips or champing of the jaw The senses of taste and smell are not lost from a unilateral lesion of this region since they are bilaterally represented in the cerebral hemispheres Recent clinical and electro encephalographic researches indicate that discharging lesions in the temporal lobes play an important part in epileptic automatism and the so called psychomotor epilepsy It also seems likely that congenital or acquired defects in the temporal lobes may be concerned with the behaviour disorders of aggressive psychopaths

The outer surfaces of the temporal lobes are concerned with hearing Lesions here may re ult in fits which are heralded by crude auditory hallucinations but owing to the complete semi decussation of the auditory path unilateral lesions never produce detectable deafness Bilateral lesions may however produce cortical deafness

In right handed subjects lesions of the left temporal lobe commonly give rise to serious disorders of speech *function With lesions situated far forward* towards the insula the disturbance is predominantly one of spoken speech With those situated in the posterior portion of the lobe the defect is predominantly one of the reception of speech Deeply situated lesions of the temporal lobe commonly produce jargon aphasia Transitory disturbances of speech may occur in focal attacks originating from lesions in this area

On account of the wide excursion which the optic radiation makes into the deep

part of the temporal lobe in its course from the thalamus to the calcarine cortex homonymous field defects especially of the upper quadrants are very common in deep seated lesions of the temporal lobes Such lesions may also produce a paresis for emotional movements of the opposite half of the face which is relatively greater than the loss for voluntary movements The occurrence of incontinence of sphincters of a mental type is occasionally seen

INTERNAL CAPSULE

In this region the chief motor tract is condensed into a small space and is situated immediately in front of a narrowly localised sensory tract while not much farther posteriorly the visual path emerges from the thalamus Lesions of this region therefore produce severe and widely spread hemiplegia of the opposite side often associated with hemianæsthesia and not infrequently with hemianopia of the opposite side From the proximity of the thalamus and corpus striatum there is often involvement of these structures in a capsular lesion with appearance of the characteristic spontaneous involuntary movements and sensory loss

THE REGION OF THE FALX CEREBRI

Lesions of this region are likely to affect both hemispheres equally Tumours opposite the paracentral lobules may cause bilateral crural monoplegia with disturbances of cortical sensibility in the feet if the post central area is involved Focal fits starting in one foot may occur Disturbances of sphincter control are occasionally seen Tumours arising from the posterior region of the falx may result in bilateral hemianopia Thrombosis of the superior longitudinal sinus may produce widespread bilateral lesions of the hemispheres with double hemiplegia in which the face and hands are usually spared

BASAL GANGLIA

OPTIC THALAMUS

A very characteristic clinical picture results from destruction by thrombosis of this structure which is termed the thalamic syndrome of Dejerine and Roussy there is hemiparesis with spontaneous involuntary movements on the side of the body opposite to the damaged hemisphere The latter may be of the nature of tremor, intention tremor choreic athetotic dancing or irregular movements Mo t post hemiplegic involuntary movements are due to a lesion of the thalamus In addition there is hemianæsthesia often with a characteristic hypersensitivity to painful thermal or other stimuli such as tickling rubbing etc which may produce agonising distress Sometimes spontaneous constant and unrelievable pain occurs on the affected side of the body Emotional movement of the face may be impaired much more than is volitional movement The thalamic syndrome is not invariably or even commonly seen when the lesion is a tumour In such cases the symptom complex varies according to whether the growth primarily ari es in the thalamus or invades it from its lateral aspect In the former case it arises in the subependymal glia and spreads laterally Such tumours are characterised by early mental deterioration with conjugate ocular palsies Sensory changes are absent or only terminal in appearance In the case of tumours secondarily invading the thalamus from its lateral side sensory changes of the order described under the thalamic syndrome of Dejerine and Roussy and by Head and Holmes are seen

CORPUS STRIATUM

Little is known with certainty of the symptomatology of focal lesions of the large masses of grey matter which form this structure The syndrome of Parkinsonism is associated with degenerative changes in the globus pallidus of both lenticular nuclei but such changes are not confined to those organs but involve other areas of the cerebral hemisphere as well The same is true of chorea and athetosis in which degenerative changes are conspicuous in the caudate nuclei However a local lesion usually vascular in a neighbouring mass of grey matter the corpus subthalamicum or corpus Luysii is followed by very violent unilateral choreiform movements on the opposite side of the body, the so called *apoplectic chorea* or hemiballismus

THIRD VENTRICLE AND HYPOTHALAMUS

Lesions occupying this cavity which are usually neoplastic may produce symptoms of localising value in addition to those resulting from obstruction of the cerebro spinal fluid circulation (hydrocephalus) The most important of these are hypersomnia diabetes insipidus obesity and alteration in primary and secondary sexual functions of a more variable character than those which occur in lesions of the pituitary body In the case of the not uncommon colloid cysts of the third ventricle which hang suspended from its roof by a short pedicle the symptoms including the obstructive hydrocephalus may be noticeably intermittent Where the posterior end of the ventricle is affected there may be disturbance of the pupillary light reflex

BRAIN STEM

THE MID BRAIN

This portion of the brain stem consists of a small dorsal area the quadrigeminal plate or tectum and a large ventral area the cerebral peduncles or crura cerebri

At the level of the corpora quadrigemina the oculo motor nuclei lie on either side of the aqueduct of Sylvius and lower down on either side of the middle line in the floor of the upper part of the fourth ventricle Lesions of this region cause nuclear ophthalmoplegia—that is paralysis of both eyes in terms of the conjugate movements upwards downwards or laterally From above downwards lesions of this column of oculo motor nuclei will produce reflex iridoplegia loss of convergence paralysis of upward, downward and lateral movements respectively

Immediately ventral to the third nerve nucleus and decussating below it lie the superior cerebellar peduncles passing to the red nuclei Involvement of these structures causes ataxy of the limbs and trunk

A lesion of the tectal region of the mid brain produces a characteristic syndrome of nuclear ophthalmoplegia with bilateral ataxy which is termed *Nothnagel s syndrome*

In the ventral portion of this region of the brain stem are the crura cerebri with the third nerve perforating each crus to emerge on its inner side and the optic tract running round the crus as it passes back from the optic chiasma to the lateral geniculate body A lesion of one crus will cause hemiplegia of the opposite side and paralysis of the third nerve on the same side This pathognomonic localising combination is known as *Weber s syndrome*

Situated a little more dorsally a lesion of the crus will produce ophthalmoplegia of one eye with tremor and inco ordination of the opposite limbs This is known as *Benedikt s syndrome*

Extension of a lesion outwards from the crus may cause tract hemianopia in which

the half fields are completely involved and the light reflex lost from the blind fields Interference with the fillet may cause hemianæsthesia on the opposite side

PONS AND MEDULLA

In these regions the motor and sensory tracts the middle and inferior cerebellar peduncles the cranial nerve nuclei and the outgoing cranial nerves are closely packed together and the signs resulting from destruction of these will be various combinations of spastic paralysis ataxy and sensory loss in the body and limbs—from interference with the long conducting tracts—together with nuclear and peripheral nerve palsies and anæsthesia in the distribution of the cranial nerves

If the lesion is unilateral the body and the structures innervated by the cranial nerves will be affected on opposite sides causing the crossed paralyses or alternate paralyses characteristic of lesions of the brain stem Of these facial palsy of lower motor neurone type with contralateral hemiplegia is the most frequently encountered trigeminal palsy and anæsthesia and vagoglossopharyngeal palsy with contralateral hemiplegia being less common Lesions of the brain stem below the oculo motor nuclei cause small pupils (pontine myosis) by cutting off those nuclei from the spinal cord whence the tonic dilators of the pupils—the cervical sympathetic system—emerge Lesions in the upper part of the pons commonly lead to loss of conjugate lateral movement of the eyes If the connections of the vestibular nerve are involved intense vertigo may result together with nystagmus at rest and on movement of the eyes Glycosuria may be met with in lesions in the neighbourhood of the fourth ventricle and the respiratory centre may be involved

The common lesion involving the medulla is softening of the lateral portion from thrombosis of the posterior inferior cerebellar artery or its branches the so called cerebellar apoplexy (see p 1440) Owing to the smallness of the brain stem lesions of an inflammatory or neoplastic character commonly involve both sides of the structure and bilateral symptoms result

CEREBELLUM

When lesions of this structure develop suddenly they are apt to produce more striking disturbances of function than when they develop gradually a point which it is important to remember when the presence of an abscess or a tumour within the cerebellum is suspected These disturbances are all in the realm of voluntary movement and the several different components of cerebellar ataxy are to be regarded not so much as special disorders of different cerebellar functions but as expressions of a single disorder which owe their varying appearance to the varying nature of the clinical tests employed

Hypotonia—This is particularly marked in acute lesions but can also be detected in those of slow evolution It shows itself by marked flaccidity and extensibility of the limb muscles which permit of undue mobility of the joints and leads to a modification of the normal posture of the limbs and when marked to the pendular form of knee jerk The hypotonia is largely responsible for the symptom of *dysmetria* If the patient is asked to extend the arm and pick up some object such as a glass or to touch a fixed point the limb is shot forward with undue force and may over shoot the mark Similarly the hypotonia may give rise to the *rebound phenomenon* If the arms be horizontally extended by the patient and the observer smartly strikes them downwards by a blow on the hand the arm on the normal side is quickly brought to rest in its original position with the minimum of recoil On the side of the lesion however the hand and arm ' bounce freely and may oscillate two or three times before being brought to rest

Dysdiadochokinesis —This name has been used to describe the slowness clumsiness and irregularity with which alternating movements (*e g* pronation supination of the forearm) are carried out although the simple movement can be performed normally In carrying out this test it is common to see adventitious movements in the proximal segments of the limb from disturbance of the normal co ordinated contraction of the adjuvant muscles To correct this disturbance the patient tends to break up complex movements into their several components which are carried out successively instead of simultaneously—the so called movement by numbers

Tremor —This is not a resting tremor but an unsteadiness which develops during movement and in purposive movements tends to increase in range and severity as the climax of the movement is reached It is thus essentially an intention' tremor

Similarly if the arms are out stretched they may show a tendency to droop, which is corrected by a series of jerks which thus gives the form of a tremor

Again standing there may be irregular oscillations of the trunk and head—the so called titubation

Gait —In bilateral lesions the gait has a reeling staggering character and in unilateral lesions there is a tendency to sway and deviate towards the side of the lesion The disorder may vary in severity from a slight unsteadiness to a complete inability to walk or stand unaided There is a tendency to walk with the legs abnormally separated to lessen the tendency to overbalance and the feet are brought down irregularly with a stamp

Speech —The articulatory musculature shares the inco ordination of the other voluntary muscles with a resulting characteristic dysarthria The defect is known as scanning or staccato speech It consists of slowness of articulation and a tendency to say each syllable of a word as though it were a separate word The rhythm of speech becomes irregular some syllables being slurred over others being enunciated with almost explosive violence

Nystagmus —Nystagmus is particularly frequent in those lesions of the cerebellum which involve its connections with the brain stem and the neighbouring vestibular nuclei In unilateral lesions there is coarse nystagmus on deviating the eyes to the side of the lesion with a finer and more rapid movement on deviation away from the side of the lesion In bilateral lesions the nystagmus may be symmetrical and if the lesion is confined to the superficial areas of the cerebellar hemispheres nystagmus may be entirely absent Rarely—usually after acute lesions such as gunshot wounds or operative interference—the phenomenon of skew deviation may appear temporarily the eye on the side of the lesion being displaced downwards and inwards the opposite eye upwards and outwards A slight degree of skew deviation on lateral deviation of the eyes may be seen in deeply seated tumours of the cerebellum

The cerebellum forms part of the non sensory afferent nervous system and is concerned with the co ordination of voluntary movement It is not a sensory organ and there is no disturbance of any form of sensibility in cerebellar lesions

THE ANTERIOR FOSSA OF THE SKULL

The lesion most commonly found in this situation is a meningioma arising from the dural covering of the cribriform plate and growing upwards into the olfactory groove The earliest sign is anosmia from pressure on the olfactory bulb and tract unilateral at first and later often bilateral Unilateral loss of vision associated with primary optic atrophy may later be associated with papilloedema in the opposite eye as an expression of the general rise of intracranial tension Such a tumour gradually displaces the overlying frontal lobe and may then give rise to mental deterioration and fits but only in tumours of exceptional size is a crossed hemiparesis observed

Aneurysm of the anterior cerebral or anterior communicating arteries may give rise to similar early symptoms but owing to its limited size papillœdema and the remote pressure effects are not seen

THE MIDDLE FOSSA OF THE SKULL

A rich variety of lesions may arise in or invade this fossa and the syndromes vary according to the situation of the lesion

The lesions in the mid line include pituitary adenomata tumours of the pituitary stalk and meningioma of the sellar diaphragm (parasellar and suprasellar tumours) In the lateral parts of the fossa passing from mesial to lateral we have to consider lesions in the cavity or walls of the cavernous sinus and tumours arising from the sphenoidal ridge in its middle and outer parts Finally reference must be made to growths invading the base of the skull and either occluding its foramina and producing cranial nerve palsies or actually invading the cranial cavity Secondary deposits of carcinoma and epitheliomata of the naso pharynx are the common lesions of the last named group

REGION OF THE OPTIC CHIASMA AND THE PITUITARY BODY

The most common lesion in this region is tumour of the pituitary usually an adenoma The earliest symptoms of such a tumour are of an endocrine disturbance and vary according to the nature of the tumour If this is composed of eosinophil cells acromegaly or gigantism will result whereas if the adenoma is composed of indifferent (chromophobe) cells the endocrine disturbance will take the form of hypo pituitarism of which Frohlich s dystrophia adiposo genitalis is the common and Lorain s infantilism the rarer type Basophil adenomata although producing a char acteristic group of endocrine symptoms commonly described as Cushing s syndrome (see p 516) do not attain a size sufficient to produce symptoms as space occupying lesions

When a pituitary tumour of whatever kind extends outside the cavity of the sella turcica it causes distortion of the optic chiasma and produces one of a variety of visual disturbances The commonest of these is a bitemporal hemianopia sometimes starting as bitemporal paracentral scotomata which gradually increase in size till the entire temporal fields are lost This results from the stretching of the decussating fibres of the chiasma derived from the nasal halves of each retina In other cases if the extension of the tumour is forward uniocular scotoma hemianopia or blindness may result while if the extension is backward homonymous hemianopia may result from involvement of the optic tract It cannot be too strongly emphasised that the form of the visual field defect in pituitary tumours is determined by the position of the local pressure upon the visual pathway and that while a bitemporal hemianopia is the most usual and characteristic defect the others which have been mentioned are frequently seen Primary optic atrophy in the affected eyes is the rule in pituitary tumours and papillœdema is not seen unless as rarely happens the tumour has attained such a size as to obstruct the third ventricle

Meningeal tumours arising from the sellar diaphragm and aneurysms extending backwards from the anterior communicating artery and cystic arachnoiditis may pro duce identical pressure symptoms but without the endocrine disorders of pituitary tumours

Cysts derived from vestiges of Rathke s pouch give rise to endocrine and local pressure symptoms comparable to those of primary intra sellar tumours but in addition give rise to papillœdema and internal hydrocephalus from obstruction of the third ventricle (see also p 1403)

SYNDROMES OF THE CAVERNOUS SINUS

The commonest acute lesion of this cavity is thrombosis usually septic Of the slowly developing lesions saccular aneurysm of the carotid artery is the most frequent though the cavity may be encroached upon by tumours originating from the mesial end of the sphenoidal ridge Symptoms consist of paresis of the third fourth and sixth cranial nerves often leading to complete ophthalmoplegia anæsthesia in the distribution of the ophthalmic division of the trigeminus and proptosis of the corresponding eye with œdema of the orbital tissues and conjunctiva from congestion of the ophthalmic veins In rapidly developing lesions unilateral papillœdema may occur but in those of slow development unilateral optic atrophy from pressure on the neighbouring optic nerve is more often seen

SYNDROMES OF THE SPHENOIDAL RIDGE

The dural sinus which runs along the sphenoidal ridge (sinus sphenoparietalis) is one of the sites of election of the development of meningiomata From the point of view of localising diagnosis this ridge may be divided into three parts the inner (or clinoidal) the middle and outer

A meningioma arising from the inner part gives rise in its early stages to a syndrome similar to that of a lesion of the cavernous sinus Later symptoms referable to pressure on the temporo sphenoidal lobe may occur (uncinate fits personality changes and crossed hemiparesis) Papillœdema may result from general increase of intracranial pressure

A meningioma of the middle part of the ridge may remain for long without clear localising signs and radiography and ventriculography may be necessary to establish its position

At the outer end of the ridge a meningioma may produce as its localising syndrome unilateral exophthalmos without squint some fullness of the temporal fossa with local tenderness on pressure speech disturbances if the lesion is left sided together with the general symptoms and signs of raised intracranial tension The X ray picture usually reveals densification of bone or even hyperostosis of a part of the ridge and adjoining bone

SYNDROMES OF THE BASE OF THE SKULL

The characteristic signs of such lesions are palsies of the cranial nerves often in groups anatomically close to one another without any evidence of intracerebral damage or rise in intracranial tension The common cause is malignant growth either secondary deposits from remote carcinomata the lung and breast being the most important, or direct invasion from the naso pharynx

THE POSTERIOR FOSSA OF THE SKULL

Lateral recess —The angle formed by the posterior surface of the petrous temporal bone and the tentorium (cerebello pontine angle) is a common situation for neuro fibromata which grow usually from the eighth nerve but occasionally from the fifth or seventh Rarely a meningioma may occupy the same position Such a tumour presses into the lateral lobe of the cerebellum and the side of the pons A highly characteristic clinical picture results consisting of slowly progressive nerve deafness and tinnitus some facial weakness usually accompanied by peripheral facial spasm impairment of sensibility in the area of the fifth nerve with diminution or loss of the corresponding corneal reflex and signs of ipsilateral cerebellar involvement Such

tumours are of slow growth and headaches and papillœdema are often absent or occur late in the clinical picture

APHASIA AND OTHER DEFECTS OF SPEECH

Speech is the most highly developed and recently evolved function of the human being which is capable of direct analysis Of all man s endowments it is the one which marks him off most clearly from his closest neighbours in the animal world While in its final expression speech consists of sensori motor activities of many mechanisms each simple in comparison with the whole its roots strike deeply into the texture of the mind and it constitutes the symbolic currency of thought itself indeed it is doubtful if without speech in this wider sense any but the simplest thoughts are possible So it is that we find that profound disturbances of speech function are invariably accompanied by disorder of the mind

Speech in its simplest form is a means of communication of thought between individuals by the production and perception of sounds but unlike sight or hearing it is an elastic function capable of indefinite extension and elaboration both in the race and in the individual We thus find an almost infinite variation between the simple language of a primitive people and the highly elaborate language of a civilised race between the speech of an uneducated peasant for whose simple needs a few hundred words suffice and that of a master of prose who may use thousands of words to express shades of meaning far beyond the scope of an uncultured person between the speech of a child and that of the same individual grown to maturity The growth of speech proceeds *pari passu* with the growth of the mind which employs it for its needs Furthermore upon the foundation of the initial symbolic expression of thought in spoken language has been erected in all but primitive races the further edifice of written speech in which visual symbols replace those of sound The evolution of speech in the different races of mankind is the province of the science of philology but its growth in the individual in health and its dissolution in disease make up one of the most fascinating and complex chapters of medicine As would be expected in a function of such complexity the disorders of speech are many and varied At one end of the scale are disturbances purely psychological in their origin such as hysterical mutism at the other are those due to the defects of the executive structures such as the tongue and larynx and the neuro muscular mechanisms which control them To disturbances of this order the term *dysarthria* is applied Between these extremes lie a group of speech disorders which depend upon physical disturbance of the portions of the cerebrum which form the anatomical substratum of the speech function and to these the terms *aphasia* or *dysphasia* are applied It is with this order of speech disturbance that we are at first concerned

APHASIA

General Considerations —Few subjects have suffered more from attempts at over simplification than the study of aphasia Many attempts have been made by the creation of hypothetical centres connected with one another by supposedly well defined tracts to explain the manifold and often apparently conflicting facts which may be observed in an aphasic patient Such diagrammatic analyses have been based upon individual cases of aphasia in which particular aspects of speech function have been predominately affected and in which post mortem examination has revealed damage to a circumscribed area of the brain Thus Broca s centre in the cortex of the posterior part of the left third prefrontal convolution was the motor centre for spoken speech while Exner s centre in a similar position in the second left

prefrontal convolution was the motor centre for written language The auditory word centre in which auditory memories of words were stored was in the cortex of the first and second temporal gyri while the ' visual word centre ' in which visual memories for words were impressed was in the cortex of the angular gyrus These various centres were connected together by to and fro pathways which could be separately affected by a lesion But the attempts to explain the multitudinous and varied phenomena which occur in lesions of the speech centre by assuming damage to one or other of these hypothetical ' word centres ' or to their connecting paths proved highly unsatisfactory, and the validity of such clinico pathological correlations was usually undermined by the fact that the majority of cases of aphasia result from vascular lesions in which multiple areas of disease are present or from tumours of wide extent

Clinical observation shows that as the function of speech in health evolves *as a whole* from more simple to more complex by a process of gradual elaboration so in disease it undergoes dissolution as a whole from more complex to more simple The more critically cases of so called pure motor aphasia or pure word deafness are examined the more clear it becomes that while one particular aspect of spoken speech is particularly affected, the level of speech function as a whole is lowered Furthermore, in a given case of aphasia the defect of function is not constant but may vary widely with the activity of the brain as a whole in response to such factors as fatigue attention anxiety and the general level of health of the whole individual

These considerations must constantly be borne in mind in the examination of aphasic patients and in our attempts to generalise from such individual observations and to obtain a clear understanding of aphasia as a whole

Anatomical Considerations —The function of speech seems to be concerned with the left hemisphere of the brain alone in right handed persons and this is explained by the major potential of the left hemisphere for receptivity and education associated with the major use of the right hand through the countless ages of humanity True left handedness is usually associated with a transfer of the speech function to the right hemisphere, but there are exceptions to this rule The possibilities of transfer of the speech function from the left to the right hemisphere is great during childhood to the extent that no lesion of the speech region of the left hemisphere however extensive causes lasting loss of speech in a child under the age of 6 years provided that sufficient intelligence remains to permit of re learning After this age the possibility of such compensation by the right hemisphere from lesions in the left hemisphere seems gradually to diminish and to occur but little after adult life is reached but even in adult life remarkable exceptions to this rule are seen Within the left hemisphere speech function has as its anatomical substratum a region of the cerebral convolutions having its centre a little behind the middle of the first and second temporal convolutions It is limited above by the posterior limits of the Sylvian fissure occupies probably most of the external convexity of the left temporal lobe and spreads backwards into the supramarginal and angular gyri while anteriorly it extends forward deep to the Sylvian fissure over all the convolutions of the insula and to the posterior ends of the second and third left frontal gyri

This speech region of the brain comprises not only the cortex but also the subcortical white matter which carries the paths of communication between the speech region and other portions of the brain Posteriorly it receives an important tract from the visual region of the cortex An interruption of this tract results in the condition known as pure word blindness ' in which the most conspicuous feature is an inability to appreciate written speech Upon its deep aspect the speech region of the convolutions receives the temporal projection of fibres conveying auditory impressions and destruction of this system by a *lesion undercutting the convolutions* in the centre of the temporal lobe results in serious speech disturbance in which

word deafness ' or inability to appreciate spoken language, is the most important component In this same region another set of fibres impinges upon the speech area which convey the muscular sense impressions and other sensory impressions which are produced in the movements of articulation and which are the only guidance which the deaf mute has in the knowledge of correct execution of his articulation A lesion deep in the temporal lobe may interrupt both the foregoing paths and so isolate the speech region from any appreciation of correct execution with the result that spoken language becomes unshapen and degenerates into a voluble jargon or jargon aphasia which is invariably associated with serious mental deterioration and confusion

In the anterior half of the speech area a tract of white fibres gathers by degrees, and passing forward constitutes the bulk of the temporal isthmus which joins the temporal lappet of the insula to the region beneath the middle and inferior frontal convolutions from whence it is connected with the pyramidal path of the left side and by way of the corpus callosum with the pyramidal path of the right side This is the executive outgoing path for speech movements and a complete lesion of this path will result in inability to exteriorise spoken or written speech with relatively little impairment of comprehension of speech—the so called pure motor aphasia or pure agraphia Within the speech area of the brain thus limited little is known of any localisation of function but it is generally held that there is a gradual passing over from receptive functions (appreciation of spoken and written language) in the posterior regions to executive functions (exteriorisation of spoken and written language) in the anterior regions

In so far as the phenomena of word blindness and word deafness as well as motor aphasia and agraphia result from lesions of the speech area they seem to result from lesions of the tracts concerned rather than from damage to the cortex itself Lesions confined to the cortex and sparing the subcortical white matter unless they are extensive do not give rise to permanent disorder of speech

Physiological Considerations —Within a short time after birth the child begins to recognise the nature and uses of some of the objects in the world around it and to express its simple conscious processes by gestures and it early appreciates the gesture language of those around it The mimesis or gesture language thus early impressed and expressed remains throughout life the most stable the least vulnerable and the longest lasting of the methods of receiving and communicating ideas Long before it is able to utter any articulate sound the infant learns to connect certain sounds which it hears with certain objects and with certain events and the memories of these auditory patterns first implanted serve by far the most important function in the processes and expressions of thought throughout life Whereas we rely upon our visual memories for our remembrance and intelligence in general matters almost exclusively yet as regards speech we rely upon auditory memories to a very large extent and of course those who have never learned to read do so exclusively The process of recall both in silent thought and in speaking is the revival of auditory patterns From the original connection with hearing the memories of speech patterns come to be located in that part of the brain associated with the auditory function—in and around the temporal lobe Later guided by the auditory memories the child begins to express himself in articulate speech and he does so by the revival of auditory memories

All living motion is sense originated sense guided and sense governed and a motor process of itself has no proved conscious concomitant Our consciousness is that of the sensations which accompany the movement or which result from the movement The knowledge of correct execution so gained fortifies and increases the functional stability of the speech area and is of immense importance in the speech function If it be absent owing to a lesion isolating the speech area on the incoming side speech degenerates into a jargon and soon becomes impossible just as in tabes

the walking becomes irregular from loss of the muscular sense conveyed in the posterior columns and ultimately standing becomes impossible

When at a considerably later age the child learns to read and to write certain visual patterns (letters words sentences) become connected with certain objects and ideas, and become linked on to the already well established auditory memories of speech The meaning of the visual symbols is learned by the child from the meaning of the word or pattern spoken which he already knows well and the already developed auditory speech function serves as the instructor of the visual speech function and throughout life remains the more potent more dominant and less vulnerable function of the two

Later still in learning to write the child relies upon his visual memories, and *as his knowledge of correct execution in writing is largely visual and only in minor* degree common sensory from the movements of the hand in writing it follows that the function of exteriorising speech by writing becomes intimately connected with and a part of the visual speech function, and is usually depressed or lost with the visual speech function as the result of disease It will thus be seen that there are not separate regions of the speech area in which the auditory memories of language and the execution of spoken speech on the one hand and the visual memories of language and the execution of written language on the other hand are represented but that there are four functions intimately coupled in pairs which have their seat in the same anatomical substratum As has already been pointed out it is a general principle that when the speech area is damaged the speech function becomes depressed as a whole with the result that function is lost in order of its depth of impression

PATHOLOGICAL CONSIDERATIONS —By far the most common cause of aphasia in all its degrees and varieties is vascular disease Thrombosis accounts for the majority of these and embolism and hæmorrhage for the minority Trauma to the speech areas of the left hemisphere may cause a wide range of aphasic disturbances Cerebral tumour is the usual lesion causing aphasia of gradual onset and is much the commonest cause of jargon aphasia ' for there are few other lesions which can undercut and therefore isolate the temporal convolutions without otherwise interfering with their function

Left sided temporal lobe abscesses constantly cause aphasia as one of their early symptoms

Symptoms —Small lesions of the cortex seldom if ever produce lasting disturbances of speech This indicates that within the speech area there is no narrow localisation of cortical function and there must be capacity for compensation for such small lesions in the surrounding undamaged cortex With larger lesions of the cortex and in proportion to their extent mutilation of the patterns of speech slowness of utterance inability to find the words (inability to recall) especially nominals and above all isolated nominals occur in that order

In the *mutilated speech of the aphasic may* be sometimes noticed stammering This condition is at once distinguishable from true jargon aphasia since the former is slow and halting whereas the latter is facile and voluble Misplacement of words and the use of wrong words are common and are called ' paraphasia A tendency to repeat a word once pronounced is sometimes present and is designated perseveration of speech The same faults occur also in writing as faulty spelling misplacement of letters and words and the use of wrong words Much defect of general intelligence always accompanies severe damage to the speech area especially if comprehension of spoken speech is involved and this will be readily understood from the very large rôle which speech patterns play in the working of thought Difficulty in the recall of words and speech patterns which has been termed verbal amnesia ' or ' nominal deficiency is a characteristic feature of lesions of the speech area This difficulty is greater with spontaneous revival than with recall which is brought about by direct sensory stimulation For example an aphasic person who is unable

spontaneously to utter a word may repeat the word at once when it is spoken to him when he sees it in writing or when the corresponding object is shown to him It is important in this connection to bear in mind that we do not speak in the letters of the alphabet, nor in the words of our dictionary but in a running pattern of sound The pattern or context provides the meaning while the individual words are negligible and have no meaning The power of the pattern in aiding revival is very great both from sequence rhythm and musical quality As an example an aphasic who has no spontaneous utterance is told to count with his interlocutor The interlocutor begins counting the aphasic joins in The interlocutor then stops but the aphasic continues counting carried by the sequence rhythm

The confusional defects of speech function are met with in extensive damage to the speech area and are usual as immediate and transient phenomena in all suddenly occurring lesions of the speech area There is general mental dullness with varying degrees usually severe of depression of speech function and much confusion both on the acceptive and expressive sides when any of these functions remain and the results of the examination of the speech faculty are apt to vary very much from moment to moment for attention is very difficult to hold and the patient is easily fatigued and bored Severe degrees of this form of defect may be associated with inability to recognise objects— object blindness and with loss of ability to convey ideas by gesture— amimia

Prognosis —In attempting to estimate the degree of recovery which is likely to occur in cases of aphasia it is necessary first to bear in mind that sudden cerebral injury is apt at first by the process which has here been described as functional depression or diaschisis to cause very wide loss of function though the lesion may not be very extensive A total aphasia for example is often the immediate result of a lesion of moderate size Such phenomena last usually not longer than a week and until they have passed off it is impossible to make a definite statement either as to the extent of the lesion or the likely degree of recovery Speech may be regained by two entirely separate processes—either by recovery of function in partly damaged and functionally depressed areas or by compensatory activity in the undamaged portions of the brain The possible recovery of function will depend upon the nature of the lesion and upon its extent It will be greater when a lesion may be judged to be one of pressure rather than of actual destruction if such pressure be removable as in subdural hæmorrhage abscess and gumma and least when widely spread arterial disease and a failing heart suggest that the lesion is a thrombosis or when an irremovable tumour is present The greater the extent of the lesion if it be presumably from vascular occlusion as judged by the associated signs paralysis anæsthesia and hemianopia the less is the chance for functional restitution as there is then little hope of any useful restoration of the circulation through collateral vessels In children under the age of 6 years unilateral lesions produce no permanent speech defects provided sufficient intelligence remains but even to this rule some important striking exceptions have been recorded When adult life is reached transference seems to occur but little yet in a few recorded instances destruction of the posterior half of the speech area has been followed by an almost complete restoration of speech function

Treatment —The recovery of speech after a lesion causing dysphasia has much in common with the original acquisition of speech in a child The preservation of a certain degree of intelligence is essential to recovery and the younger the patient the greater the prospect of a successful outcome It is an unfortunate fact that the majority of cases of dysphasia occur in elderly subjects with arterial disease or in persons with infiltrating tumours in whom a gradual deterioration of cerebral function must be expected The most hopeful group are the young adults and children suffering from traumatic lesions of the brain or such transient cerebral lesions as subdural hæmatomas cerebral abscesses angiomatous malformations and benign tumours In such

cases spontaneous recovery of speech occurs gradually but it can be accelerated by a careful and patient system of re education at the hands of a speech therapist carried out either individually, or in groups

METHOD OF EXAMINATION —In examining a dysphasic person certain principles must be kept constantly in mind The patient is always anxious and easily alarmed He fatigues readily and is abnormally emotional and distractable It thus follows that he should be examined *in a quiet and physically comfortable environment* should be treated with gentleness and should only be examined for short periods such as half an hour at any one time

It should be remembered that dysphasia like all manifestations of disordered *cortical function varies in severity and quality from hour to hour and almost from* minute to minute in response to such varied factors as attention, fatigue and general bodily well being

It follows that the best record of an examination of a dysphasic patient is an *objective and factual one* a statement of what the examiner said or did and what the patient said or did in reply

Before any detailed investigation is attempted certain facts should be established and when possible confirmed from a relative (1) Is the patient right or left handed and if the latter, did he write with the right hand ? (2) What was his state of education as regards reading writing and knowledge of foreign languages ? (3) Is he deaf ? If so to what extent ? (4) Is his sight good or bad ? Is there hemianopia ? (5) Can he understand pantomime or gesture and express his needs thereby ? (6) What is his state of consciousness ? (7) To what extent is propositional speech preserved and to what extent can he convey a narrative in words ? What defects are evident *e g* perseveration paraphasia or jargon utterances ? (8) Can he name objects seen both simple and familiar and unfamiliar ? (9) Can he obey spoken commands ? (10) Can he select correctly a test object from a number of them in respon e to the spoken word ? (11) Can he write spontaneously and to dictation and what mistakes does he make ? (12) Can he copy printed or written words ? (13) Can he obey written commands ? (14) Can he write figures and carry out simple arithmetic calculations ? (15) Can he understand the significance of pictures ? (16) Can he draw such simple objects as a bicycle a flower or the façade of a house

Having obtained some insight into the patient s speech defect in a preliminary survey it is essential to assess *the degree of mental deterioration (if any)* that is present by the battery of tests employed to investigate a case of organic dementia since dysphasia and global mental deterioration each in its way increases and distorts the severity of the other

TESTAMENTARY CAPACITY —*No rule can be laid down as to the capacity* of a person suffering from aphasic speech defects to exercise civil rights and to make a will and each case must be judged upon its merits The first and all important consideration is the degree of intelligence and when this is good it is essential for such capacity that *there should be some mode of cognition and of expression left* In cases of uncomplicated executive aphasia either for spoken or written speech there is complete civil capacity but when as usually happens the two conditions coexist though intelligence and the receptive side of speech may be but little impaired yet *the expressive side of speech is reduced to gesture* and extreme difficulty may be met in ascertaining the patient s wishes Defects in the comprehension of spoken and written speech interfere seriously with testamentary capacity and with capacity for exercising civil rights In such cases there is great loss both on the acceptive and on the expressive *sides of speech with confusion of memory* and impairment of intelligence Most satisfactory results have however many times been brought about in apparently hopeless cases by careful sympathetic and repeated procedures in which the properties to be bequeathed and the likely legatees are assembled before *the patient thus allowing* the testator to match the gift with the recipient The

proceedings should be conducted in the presence and under the direction of a physician thoroughly conversant with the subject of aphasia All concerned should bear two points in mind, the one being that the wishes of the testator must be paramount, and the other that an obviously just will is most difficult to upset in a court of law

DYSARTHRIA

The conversion of mentally formulated speech symbols into spoken language requires the correct use of several mechanisms concerned respectively with the production of the voice by the passage of a stream of air through the aperture between the vocal cords and the articulation of words by movements of the lips tongue palate and jaws To defects of speech dependant upon disorders of these executive processes the term dysarthria is applied The neuro muscular mechanisms responsible for these movements are built upon the same principles as those which control other highly co ordinated voluntary movements for example those of the hand Impulses originating in the appropriate areas of the cerebral cortex are transmitted through the pyramidal tracts to the lower motor neurones (in the case of speech the various bulbar nuclei) and from these a further relay of impulses proceeds through the various peripheral nerves to the muscles concerned As in other movements the co ordination of these impulses is dependant upon the simultaneous reception of afferent impulses from the muscles and organs themselves and upon the activity of the cerebellum and other subcortical centres We thus find that the varieties of dysarthria are strictly comparable with the disturbances of voluntary movement encountered in the limbs

As we have seen impulses from the executive areas of the speech cortex are trans mitted to the lower centres through both pyramidal tracts and in consequence speech disturbances do not result from unilateral lesions of the pyramidal tract in the centrum ovale or brain stem If however both pyramidal tracts are damaged as commonly occurs in diffuse vascular degeneration double hemiplegia degenerative lesions of the pyramidal system diplegia tumours of the brain stem and in advanced cases of disseminated sclerosis the characteristic disturbance known as *spastic dysarthria* results Here the speech is slow, stiff and laboured Words are squeezed out with great effort as if through a rigid mechanism and are poorly formed on account of the stiffness and paucity of movement of the lips tongue and palate This condition is often referred to as pseudo bulbar palsy (p 1443)

When the lower motor neurones subserving the speech mechanisms are bilaterally affected *flaccid or atrophic dysarthria* results The speech is slurred indistinct and often slightly nasal Labial and dental sounds are especially affected but the laboured character of spastic dysarthria is absent Atrophic dysarthria is met with in lesions of the medulla oblongata of all kinds in progressive muscular atrophy and in multiple lesions of the bulbar nerves such as peripheral neuritis Spastic and atrophic dysarthria are characteristically found in combination in those cases of motor neurone disease in which both pyramidal and lower motor neurones are undergoing decay Primary weakness of the articulatory muscles may result in dysarthria This is met with in myasthenia gravis where the muscles are subject to excessive fatiguability and in some cases of myopathy where there may be great weakness of the muscles of the lips and jaws

Ataxic dysarthria is most characteristically heard in cerebellar disease especially when both sides of the organ or its afferent and efferent pathways are damaged as in Friedreich s disease disseminated sclerosis cerebellar degeneration and exten sive vascular or neoplastic lesions of the cerebellum and pons In mild cases speech becomes slow and deliberate with faulty spacing and accentuation of syllables the

so called "scanning" or staccato speech so common in disseminated sclerosis When more severe speech becomes explosive some syllables being slurred and almost inaudible others being produced with a gush of uncontrolled sound This coarse form of cerebellar dysarthria is most often met with in Friedreich s disease and in acute vascular lesions of the cerebellum and brain stem Dysarthria resulting from loss of afferent impulses from the periphery is rare but is occasionally met with in severe cases of peripheral neuritis and of tabes Conditions associated with involuntary movements may result in severe speech disturbance This variety of dysarthria is most commonly met with in cases of chorea and athetosis but may occur in other varieties of striatal disease, or as a sequela of encephalitis lethargica In Wilson s disease (p 1484) dysarthria results from muscular rigidity and goes on to complete anarthria A very characteristic variety of dysarthria occurs in general paresis, speech is slow and slurred and tremulous and there is a tendency to repeat or reverse the order of the syllables in polysyllabic words A very similar disorder may be met with in cases of chronic alcoholism and in some varieties of drug intoxication especially barbiturate poisoning

OTHER DEFECTS OF SPEECH

STAMMERING OR STUTTERING

A spasmodic defect of articulation leading to a sudden check in the utterance of words or to a rapid repetition of the consonantal sounds in connection with which the difficulty arises To the trouble of articulation are often added spasmodic movements of face and head or indeed of any part of the body

Except in the rarest instances this condition is not associated with any structural change in the nervous system or in the organs of articulation, but it has been observed as the end result of a lesion of the speech areas It occurs with a greater frequency than can be attributed to coincidence in naturally left handed persons who have been trained to behave as if they were right handed It not infrequently occurs in more than one member of a family but whether this implies a hereditary or environmental influence is uncertain as it may equally be acquired by a susceptible subject from other members of a child group The stammerer usually manifests one or other of a number of signs of incipient psychoneurotic instability such as abnormal timidity and excitability nocturnal enuresis night terrors and habit spasms, and though these symptoms may recede or disappear with time the stammerer remains more liable than normal individuals to develop neurotic manifestations under circumstances of stress

The disorder seems to consist of a lowering of the functional stability of the executive mechanism of speech by the effect of embarrassment either at a conscious or unconscious level It is begotten of shyness and self consciousness and probably for this reason is infinitely commoner in boys than in girls for the latter are much less liable to self consciousness It is never present in infancy or very early childhood but arises at the age when shyness and self consciousness first manifest themselves Its onset not uncommonly follows a debilitating illness such as measles diphtheria or whooping cough and it often appears after a sudden fright or an experience causing severe emotional strain or embarrassment Indeed it is the historical utterance of fright and of those who find themselves suddenly *in flagrante delictu*

Like other manifestations of anxiety in childhood it is more likely to occur in homes where there are disturbing factors such as parental discord favouritism and jealousy over indulgence or over strictness and frequent changes of teachers and surroundings

The stammerer never stammers in the speech of thought nor when talking aloud to himself alone nor at any time when singing for in the two former cases the embarrassment of self consciousness is absent and in the last case the element of rhythm and music greatly increases the stability and confidence of the function of speech In rebellious cases this element of self consciousness as well as the more overt evidences of psychological instability may gradually disappear while the stammer remains unaltered as an ineradicable habit

In articulate speech three muscular mechanisms are concerned (1) the respiratory mechanism for supplying the blast of air (2) the larynx for producing the voice and (3) the muscles of the lips tongue jaw and palate for articulation For distinct speech there must be absolute co ordination of these mechanisms one with another Consonants are in nearly all cases the source of the difficulty in stammering and while these are buccal sounds yet some begin with a laryngeal sound while others are purely buccal The former are termed ' voiced consonants ' and are B W V Zh Z Th (as in thus) D L R G Y and the latter ' voiceless consonants and are P F Th (as in thin) S Sh T, K while N M and Ng terminal are voiced nasal resonants ' If one articulates these consonants it becomes at once clear and it is the presence of the initial laryngeal element or voicing which makes the difference between B V Z D G and P F S T K respectively

A careful attention to the manner in which the letter sounds are produced is absolutely essential in the investigation and treatment of stammering The difficulty occurs most commonly with the explosive consonants P B T D G K and nearly always where these occur as initial letters—that is in starting the articulatory mechanism and to avoid this difficulty which arises after every pause most stammerers speak in a rapid monotonous fashion The fault chiefly lies in the direction of energy to articulation rather than to phonation The patient held up by his stammer usually remains silent but occasionally having produced the first sound he continues to repeat it—the reduplication stammer which has been the origin for the names stammer or stutter by which the malady is known Often the patient uses a trick or contortion to prevent the stutter or to relieve the feeling of nervous tension and embarrassment in consciousness which the defect causes and these tend to become engrafted on him as (1) associated sounds—whooping grunting crowing etc (2) habit spasms—contortions of the face limbs or body which sometimes take a complicated form and exactly resemble the co ordinated form of tic

Prognosis —The majority of the cases tend to a spontaneous cure and recovery is hastened in all cases by systematic treatment In every class of case the results of treatment may come slowly at first but perseverance will in almost every case bring success

Treatment —Attention should be paid to conditions of general health and to the mental well being and satisfaction of the child with plenty of scope for pleasure and for satisfying occupation When possible defects in the home and school environment should be eliminated Speech training at the hands of a trained speech therapist either individually or preferably in special classes is invaluable It is well for the patient to speak, read or recite in a large room alone loudly slowly and distinctly The following system for such exercises is useful (1) The chest must be kept well filled with air This most important point is often most difficult to the patient. (2) He must speak slowly with a full resonant voice (3) When he comes to the word on which he tends to stutter he should raise his voice and direct his energies to vocalisation and not to articulation If the difficulty be over a voiced consonant, he must be directed to voice it firmly If the consonant over which he stumbles be a voiceless one attention must be directed to the vocalisation of the subsequent vowel sound for instance in pat he must attempt to vocalise the at and he will find little difficulty in prefixing p as the syllable is uttered (4) Gymnastic and singing exercises are valuable additions to treatment Should associated movements be

so called 'scanning' or 'staccato' speech so common in disseminated sclerosis. When more severe speech becomes 'explosive', some syllables being slurred and almost inaudible others being produced with a gush of uncontrolled sound. This coarse form of cerebellar dysarthria is most often met with in Friedreich's disease and in *acute vascular lesions of the cerebellum and brain stem*. *Dysarthria resulting* from loss of afferent impulses from the periphery is rare but is occasionally met with in severe cases of peripheral neuritis and of tabes. Conditions associated with involuntary movements may result in severe speech disturbance. This variety of dysarthria is most commonly met with in cases of chorea and athetosis but may *occur in other varieties of striatal disease* or as a sequela of encephalitis lethargica. In Wilson's disease (p. 1484) dysarthria results from muscular rigidity and goes on to complete anarthria. A very characteristic variety of dysarthria occurs in general paresis; speech is slow and slurred and tremulous and there is a tendency to repeat or reverse the order of the syllables in polysyllabic words. A very similar disorder may be met with in cases of chronic alcoholism and in some varieties of drug intoxication, especially barbiturate poisoning.

OTHER DEFECTS OF SPEECH

STAMMERING OR STUTTERING

A spasmodic defect of articulation leading to a sudden check in the utterance of words or to a rapid repetition of the consonantal sounds in connection with which the difficulty arises. To the trouble of articulation are often added spasmodic movements of face and head or indeed of any part of the body.

Except in the rarest instances this condition is *not associated* with any structural change in the nervous system or in the organs of articulation but it has been observed as the end result of a lesion of the speech areas. It occurs with a greater frequency than can be attributed to coincidence in naturally left handed persons who have been trained to behave as if they were right handed. It not infrequently occurs in more than one *member of a family* but whether this *implies a hereditary* or environmental influence is uncertain as it may equally be acquired by a susceptible subject from other members of a child group. The stammerer usually manifests one or other of a number of signs of incipient psychoneurotic instability such as abnormal timidity and excitability, nocturnal enuresis, night terrors and habit spasms and *though these symptoms may* recede or disappear with time *the stammerer* remains more liable than normal individuals to develop neurotic manifestations under circumstances of stress.

The disorder seems to consist of a lowering of the *functional stability of the* executive mechanism of speech by the effect of embarrassment either at a conscious *or unconscious level*. *It is begotten of shyness and self consciousness* and probably for this reason is infinitely commoner in boys than in girls for the latter are much less liable to self consciousness. It is never present in infancy or very early childhood but arises at the age when shyness and self consciousness *first manifest them*selves. Its onset not uncommonly follows a debilitating illness such as measles, diphtheria or whooping cough and it often appears after a sudden fright or an experience causing severe emotional strain or embarrassment. Indeed it is the historical utterance of fright and of those who find themselves suddenly *in flagrante delictu*.

Like other manifestations of anxiety in childhood it is more likely to occur in homes where there are disturbing factors such as parental discord, favouritism and jealousy, over indulgence or over strictness and frequent changes of teachers and surroundings.

If with the lumbar puncture needle and manometer in position the right jugular vein is firmly compressed an immediate rise in the level of the fluid in the manometer will be noted in the normal person the pressure rising rapidly from the normal 80 to 120 mm to 300 mm or more On releasing the compression of the jugular the pressure rapidly returns to its former level If there is any block in the spinal subarachnoid space such as may be caused by extradural compression or a spinal tumour or if there is interference with the escape of fluid from the cranial cavity there will be no rise in the pressure of the lumbar fluid on jugular compression (complete block) or a rise of only a few cms (incomplete block) In the latter case release of the jugular compression will be followed by a very slow return of the meniscus to the former level or the level may remain unaltered indicating a ball valve type of obstruction Again if the withdrawal of a small quantity (4 to 8 ml) of fluid is followed by a persistent fall in the pressure of about 50 per cent there is probably obstruction to the normal flow of cerebrospinal fluid These two tests afford valuable evidence of any occlusion of the spinal subarachnoid space

Appearance of the Cerebrospinal Fluid —Any departure from the normal watery appearance of the cerebrospinal fluid is readily detected The fluid may be freely blood stained in cases of recent subarachnoid or cerebral hæmorrhage or of trauma to the brain In such cases the blood is usually present in large amounts and is intimately mixed with the cerebrospinal fluid in all specimens removed Blood contamination resulting from faulty technique in withdrawing the fluid can usually be recognised as it is usually scanty in amount and varies in intensity in different specimens If the blood has been mixed with the fluid for more than a few hours before withdrawal it assumes a slightly orange tint on account of the break down of the blood pigment Such a specimen if centrifuged or allowed to stand will give a bright canary yellow supernatant fluid a condition known as *Xanthochromia* In cases punctured several days after a severe subarachnoid hæmorrhage the fluid may be thick and brownish orange in colour In addition to cases of resolving subarachnoid hæmorrhage xanthochromia may be present in cases of long standing spinal blockage subdural hæmorrhage some cases of polyneuritis and occasionally in cases of cerebral tumour It is often associated with a great increase in protein content of the fluid, which may thus undergo spontaneous clotting on withdrawal

The combination of xanthochromia with greatly increased protein content of the cerebrospinal fluid and evidence of spinal block is known as *Froin s syndrome* (*loculation syndrome*) and is very characteristic of severe spinal compression

Turbidity of the cerebrospinal fluid is caused by the presence of a great excess of cells and is thus characteristic of meningitis It may vary in degree from slight opalescence to a frankly purulent fluid

Increase of Protein Content —This is of great importance and occurs in many pathological conditions of the central nervous system As has already been stated it may result from occlusion of the subarachnoid space from any form of spinal block It occurs in all cases of meningitis whether pyogenic, tuberculous or syphilitic It is one of the earliest changes in the fluid in cases of cerebral abscess It may be found in acute poliomyelitis and most virus diseases of the nervous system but it is slight or absent in encephalitis lethargica An isolated increase in protein content occurs in many cases of intracranial tumour particularly where the tumour impinges upon the surface of the brain or the walls of the ventricles It may be met with after vascular lesions of the brain even though there has been no escape of blood into the subarachnoid space and also in cases of acute infective polyneuritis

Increase in Cell Content —An increase in the cell count of the cerebrospinal fluid is found in almost all inflammatory diseases of the nervous system In pyogenic meningitis an enormous excess of cells is the rule and the vast proportion of the cells are polymorphonuclear leucocytes A small number of lymphocytes may also be present and the proportion of these gradually increases as recovery takes place A

The normal cerebrospinal fluid is a clear colourless fluid indistinguishable in appearance from water and it has a remarkably constant composition As obtained by lumbar puncture it contains from 0 to 5 cells (endothelial cells and lymphocytes) per c mm Its chemical composition is as follows

Protein (mainly albumin)	0 02 to 0 04 per cent	(20 to 40 mg per 100 ml)
Glucose	0 05 to 0 09 ,,	*(50 to 90 mg per 100 ml)*
Chlorides (as NaCl)	0 72 to 0 75 ,,	(720 to 750 mg per 100 ml)

In health the globulin content is insufficient to give a positive Nonne Apelt or *Pandy test*

LUMBAR PUNCTURE

The method by which the cerebrospinal fluid is best withdrawn for diagnostic or therapeutic purposes is by lumbar puncture The patient should lie in the left lateral position with the head supported by one pillow and at the same level as the lumbar spine A firm couch or operating table is to be preferred and if the operation is performed on the patient s bed the introduction of fracture boards under the mattress is advisable The patient s back must be in a vertical plane The knees are drawn well up to produce the maximum convexity of the spine, but the neck should not be sharply flexed *or pressure measurements will be inaccurate* The site of lumbar puncture is the midline in the interspace between the third and fourth or the fourth and fifth lumbar spines The skin should be anæsthetised with local anæsthetic and the lumbar puncture needle should be introduced accurately at right angles both to the longitudinal and transverse axes Pointing the needle even slightly upwards downwards or towards the side is likely to result in contamination of the fluid with traces of blood The whole procedure must be carried out with the utmost *attention to asepsis, and the precautions taken should not be less than those necessary* for a major surgical operation The needle thus introduced will be felt to penetrate in turn the spinous ligament and the dura mater and on withdrawing the stilette the fluid will flow freely in the normal subject at the rate of about 3 drops a second In the rare cases where lumbar puncture is impossible or inadvisable cerebrospinal fluid may be obtained either by cisternal puncture or by direct tapping of the cerebral ventricles

Pressure of the Cerebrospinal Fluid —This can only be ascertained by actual measurement with a manometer, estimates based upon the rate of flow are fallacious When it is necessary to measure the pressure a three way needle with manometer attachment should be employed and before the readings are taken the patient must be lying relaxed and comfortable with easy respirations The normal pressure of cerebrospinal fluid varies from 60 to 150 mm and will be seen to rise and fall over a distance of 5 to 10 mm with the respiratory movements Coughing and straining give rise *to an abrupt increase in the pressure of from 30 to 50 mm* A pressure of over 150 mm is evidence of increased intracranial pressure and readings of over 300 mm are common in the presence of intracranial tumours meningitis and other conditions characterised by raised intracranial pressure When the cerebrospinal pressure is found to be 300 mm or more fluid should be withdrawn slowly and in the minimum quantity necessary for pathological investigation (5 ml) as the rapid withdrawal of a large quantity of fluid may result in sudden death from the formation of a medullary pressure *cone or from uncinate herniation*

Queckenstedt s Phenomenon —In the normal subject the pre sure of the fluid in the lumbar sac directly reflects the pressure within the cerebral subarachnoid spaces and the ventricles and any change in the intracranial pressure is immediately transmitted through the patent subarachnoid space and causes a change *in the level* of the fluid in the manometer This forms the basis of the valuable test for patency of the subarachnoid space known as Queckenstedt s test

this relation exists the blow on the head has simply served to bring a pre existing tumour into symptomatic prominence by causing either œdema or hæmorrhage in its substance or vicinity It must be remembered in this connection that a cerebral tumour may exist for a long period without definite symptoms

Pathology —The pathological classification of intracranial tumours has a practical importance for when the nature of a new growth can be determined clinically some idea of its future behaviour can be formed and the surgeon can make his plans to meet the problems which each variety of tumour presents

The chief varieties of intracranial tumour are as follows

Tumour of the brain substance—Glioma
Tumour arising in the meninges or nerve sheaths {Meningioma / Neurofibroma}
Secondary carcinoma and sarcoma
Blood vessel tumours
Tumour of the pituitary body and stalk
Infective granuloma—Tuberculoma Syphiloma
Parasitic and other cysts

It is not possible to indicate with precision the relative incidence of these different types of tumour for the figures available from different institutions must reflect their particular circumstances and are not representative of the population as a whole But it is possible to state that glioma constitutes about 40 per cent of all intracranial tumours and meningeal and pituitary tumours together from 20 to 30 per cent Formerly the incidence of secondary carcinoma was said to be about 6 per cent but recent evidence has indicated that it is much higher and may well be as high as 20 per cent. of the total There can be no doubt that as greater precision in diagnosis is reached the frequency of this complication of visceral carcinoma becomes more fully recognised

GLIOMA —As its name implies the glioma is a tumour arising in the glial or supporting tissue of the brain but within the limits of this term are included growths of very varied cytological type and modes of growth Some are richly cellular highly vascular and rapidly growing others are relatively acellular and may be exceedingly slow in growth But they have certain important characteristics in common They originate within the substance of the nervous system and all infiltrate to a greater or less extent the surrounding nerve tissue They are thus invariably locally malignant They do not invade tissue outside the nervous system or cause metastases in other parts of the body though in some fragments may become detached and be carried in the cerebrospinal fluid to distant parts of the subarachnoid space and there continue their growth as distinct implantation tumours Gliomas are prone to undergo degeneration and necrosis If this is rapid it may lead to cyst formation if it is slow it may lead to calcification within the tumour Hæmorrhages into the substance of a glioma are common and the surrounding brain tissue is often œdematous Occasionally gliomas are multiple

Many types of glioma have been described but these classifications are ephemeral and largely artificial for more than one pathological type may be represented within a single tumour and the same tumour may present different features at successive periods of its course But with this reservation it is useful to recognise certain common and relatively well defined clinical and pathological types

Astrocytoma is the commonest of all gliomas and is a diffusely infiltrative tumour of the white matter which occurs at all ages and in any part of the brain Its structure is relatively uniform and its growth often very slow The survival period after local removal may be long especially when as in the cerebellum a satisfactory excision of the surrounding tissue can be achieved

lymphocytosis is characteristic of tuberculous and syphilitic meningitis and of most virus infections of the nervous system In tuberculous meningitis a mixed cytosis often occurs at first with as high a proportion as 40 per cent of polymorphonuclear cells, but as the disease progresses the proportion of lymphocytes steadily rises until they represent 90 per cent or more of the total cell count A mixed pleocytosis is also seen in cases of cerebral and extradural abscess, in sinus thrombosis and after extensive cerebral softenings

Decrease in Glucose Content —The glucose content of the cerebro spinal fluid is decreased in varieties of meningitis particularly in those due to pyogenic organisms in which case the fluid commonly fails to reduce Fehling s solution on boiling It is almost invariably reduced in tuberculous meningitis but only rarely in meningitis due to viruses (see p 1396) It is also reduced in some cases of neurosyphilis

Alteration of Chloride Content —The chloride content of the cerebrospinal fluid is lowered in all cases of purulent or tuberculous meningitis largely as a result of the diminution of the plasma chlorides, which occurs in these as in other acute febrile illnesses This change is of particular value in the diagnosis of tuberculous meningitis in which affection levels as low as 600 to 650 mg per cent may be found early in the disease in contrast to the relatively normal chloride content in the case of other diseases causing a lymphocytic pleocytosis

An increase in the chloride content as well as that of non protein nitrogen is found in uræmia and other conditions of salt retention

Lange s Colloidal Gold Reaction —In neurosyphilis and in some cases of disseminated sclerosis the globulin fraction of the total protein of the cerebrospinal fluid increases and may almost equal the albumin fraction The high globulin content gives the fluid a power of precipitating colloids from suspension The estimation of this power in relation to colloidal gold is the basis of Lange s test To 10 dilutions of cerebrospinal fluid (from 1 in 10 to 1 in 10 000) constant amounts of colloidal gold are added and the mixtures allowed to stand for 24 hours The form of the precipitation curves has a differentiating value Thus in general paralysis the first 6 dilutions are precipitated (paretic curve) in tabes dorsalis the third and fourth dilutions show the maximal precipitation (luetic curve) in meningitis the sixth to eighth dilutions are precipitated (meningitic curve) In disseminated sclerosis the combination of negative Wassermann reactions in blood and fluid and a paretic curve in the fluid is frequently found

Organisms —The nature of the organismal content is determined (1) by the direct examination of films made from the centrifugalised fluid (2) by cultures from the fluid and (3) by the inoculation of animals with the fluid

The Wassermann Reaction —This is positive in all conditions of recent syphilitic disease impinging upon the meninges and always in general paralysis Though often positive in tabes it may be found negative

INTRACRANIAL TUMOURS

Under this heading are grouped all new formations which encroach upon the intracranial space and which produce the familiar pressure symptoms and local symptoms of tumour though some of them are not strictly speaking neoplasms

Ætiology —The brain is one of the commonest seats of new growth in the body Further new growth is one of the commonest forms of structural disease of the brain—second only in incidence to lesions of vascular origin

Cerebral tumour may occur at any age but it is relatively rare in the very young and in the very old There is no significant difference in its incidence in the two sexes The relation between head injury and the first symptoms of cerebral tumour is one that has often been pointed out though it is likely that in most cases where

occur in the cerebellum and give rise to blood cysts They may be associated with similar tumours in the retina and may be familial—a combination often known as Lindau s disease

PITUITARY TUMOURS —These arise from the glandular elements of the pars anterior They usually take the form of an adenoma and may be composed of any of the three types of cell found in this body

The commonest is the chromophobe (neutrophil) adenoma consisting of a mass of neutrophil cells with clear vesicular nuclei lying in masses in a fine connective tissue stroma or occasionally arranged in columns or in a primitive alveolar formation This type of tumour is associated with symptoms of hypopituitarism The less common variety is composed chiefly of cells of acidophil type whose cytoplasm contains acidophil granules of varying size This type is associated with the clinical picture of acromegaly Both the foregoing varieties of adenoma commonly attain a sufficient size to expand the sella turcica and to escape from it to cause neighbourhood symptoms by involving the optic chiasma or the oculomotor nerves The rarest type of adenoma is that composed of cells containing coarse or fine basophil granules—the basophil adenoma associated with Cushing's syndrome This is a tumour of small size which may only be detected by making serial sections and never causes expansion of the sella or symptoms of involvement of neighbouring structures Very rarely pituitary adenomata may undergo malignant degeneration, and occasional examples of tumours of mixed cell type are met with

Another tumour arising in association with the pituitary body is the Rathke pouch or supra sellar cyst (adamantinoma) This arises from cell rests derived from the buccal outgrowth (Rathke s pouch) from which the anterior lobe of the pituitary is developed Such tumours are commonly situated above the sella turcica but may be partially or wholly intra sellar They are partially solid partially cystic tumours composed of masses of transitional epithelium lying in a fine connective tissue stroma and containing cystic spaces They frequently undergo degeneration and subsequent calcification and may reach the size of a golf ball and so come to protrude far into the floor of the third ventricle and obstruct its cavity so producing a severe degree of hydrocephalus

CHOLESTEATOMATA —These sometimes called mother of pearl tumours on account of their glistening appearance are found in connection with the basal meninges Their origin is uncertain They are of slow growth and may run a symptomless course They consist of a greasy greyish friable and more or less laminated mass made up of layers of a closely packed mosaic of flat polygonal cells The tissue is necrotic and contains no blood vessels

Among the rarer tumours of the brain may be mentioned dermoid tumours teratomata chordomata, which arise from rests of the anterior end of the primitive notochord and are found below the base of the brain lipomata fibromata neuromata neuroblastomata consisting actually of undifferentiated nerve cells and enchondromata

CYSTS —Cysts of the following varieties may be met with on the surface or in the substance of the brain (1) Serous cysts of the arachnoid These may occur as part of a diffuse arachnoiditis or may occur alone without any known cause (2) Porencephalic cysts These commonly result from softening after embolism or thrombosis or severe brain injury in early childhood They may lose all trace of their origin and form thin walled cavities containing colourless fluid which often extend from the ependyma to the pia mater and involve the whole thickness of the pallium (3) Cysts derived from tumours—especially gliomata and secondary carcinomata The tumour giving rise to such a cyst may be extremely small and may appear as a small nodule in one part of the circumference Such cysts contain a highly albuminous fluid which is often yellow in colour (4) Blood cysts which are usually derived from highly vascular tumours but may follow trauma or intracerebral hæmorrhage from

Glioblastoma multiforme is a tumour only slightly less common than the astrocytoma but is far more cellular rapidly growing and varied in its histological appearance It is a tumour of the cerebral hemispheres, and although it may occur at any age is commonest in middle age or later and usually terminates life within a year of its first symptoms Because of its invasive nature it is of all gliomas the least amenable to surgical removal

Medulloblastoma is a highly cellular and rapidly growing tumour almost confined to the roof of the fourth ventricle and cerebellum It is commonly found in children and is in the form of glioma most often spread by implantation across the subarachnoid space

Other varieties of glioma are described in relation to the ependyma choroid plexus and oligodendroglia

MENINGIOMA OR ENDOTHELIOMA —This is a connective tissue tumour which grows from the endothelial cells of the arachnoid villi particularly where these penetrate the walls of the dural venous sinuses Meningiomas are therefore found in the neighbourhood of the venous sinuses especially the superior longitudinal the spheno parietal the petrosal and circular sinuses They do not invade the brain but compress and displace it and may become deeply embedded in it They may infiltrate the overlying bone which may become so thickened that a visible or palpable boss is present on the surface of the skull Meningiomas are highly vascular tumours, and large nutrient vessels may be present in the neighbouring skull and scalp Calcification in the substance of these tumours is common

NEUROFIBROMA —This also is a connective tissue tumour arising from the sheaths of the cranial nerves The vast majority grow from the sheath of the auditory nerve and constitute the common tumour of the lateral recess—the acoustic neurofibroma Occasionally they grow from the fifth or other cranial nerves The neurofibroma may be solitary or may appear as part of a generalised neurofibromatosis when it is often bilateral on the acoustic nerves It is a firm nodular tumour which gradually buries itself in the side of the brain stem and often erodes the bones of the internal auditory meatus It is usually of very slow growth but may undergo necrosis and cyst formation

SECONDARY CARCINOMA —As has already been indicated secondary carcinoma is probably more common than is generally realised It is a frequent event in lung cancer which forms the most important source of brain metastases and it is not uncommon for symptoms of secondary involvement of the brain to precede those of the primary growth in the lung

Indeed in all adult cases presenting the signs and symptoms of intracranial tumour the possibility of carcinomatous metastasis should be explored particularly in a patient who is losing weight or deteriorating rapidly

Other common sources of metastatic tumours are the breast prostate and gastro intestinal tract

Carcinomatous deposits are commonly blood borne and multiple and are liable to undergo necrosis and cyst formation and hæmorrhage

Rarely they may reach the brain by direct invasion from the naso pharynx In exceptional cases there may be a diffuse infiltration of the subarachnoid space with carcinoma and when it occurs alone this meningitis carcinomatosa may be very difficult to diagnose

BLOOD VESSEL TUMOURS —Tumours and congenital anomalies of the blood vessels are relatively common in the brain compared with other organs They take two principal forms (1) angiomatous malformations consisting either of arterio venous varices or telangiectases These are most often found in the hemispheres but may occur in the brain stem or cerebellum They involve the brain diffusely particularly on its surface and may present themselves as tumours or as cases of cerebral hæmorrhage (2) True angiomatous neoplasms or hæmangioblastomas which commonly

is thus favourably placed to produce internal hydrocephalus In elderly persons on the other hand the picture of a tumour is apt to be blurred general signs are late in development and focal signs are indistinct Possibly the presence of a background of cerebral arterial degeneration and its associated cerebral changes are responsible for this blurring of clinical outline It may be supposed that the tumour does not write its mark upon a clean slate when arterial and cerebral degeneration are already present

GENERAL MANIFESTATIONS —These symptoms are the result of an increase in intracranial pressure and are therefore absent in cases of tumour where the pressure remains normal The degree to which a cerebral tumour causes an increase in intra cranial tension is very variable and depends upon a number of factors The growing tumour by its bulk occupies a portion of the available intracranial space which is a constant and therefore after displacing cerebrospinal fluid the tumour causes directly a rise in pressure Many tumours from their position interfere with the free flow of fluid through the ventricular system and thus produce an obstructive hydrocephalus This accounts for the rapid increase of pressure seen in tumours of the cerebellum mid brain and third and fourth ventricles Other tumours may interfere with the normal venous return from the hemispheres and so produce œdema of the brain tissue with a proportionate increase in its bulk These different factors often reinforce one another and thus set up a complex vicious circle This in large measure explains the undoubted fact that a given tumour of rapid growth gives rise to much greater increase in intracranial pressure than does one of similar size and position which has developed slowly

The general manifestations of increased intracranial pressure consist of the following papillœdema headache vomiting mental drowsiness and loss of vivacity double vision alterations in the pulse rate blood pressure and respiration giddiness nasal irritation and occasionally generalised convulsion

Papillœdema —This is by far the most constantly present of all the general manifestations Papillœdema appears to be a stasis œdema of the nerve head owing to the increased intracranial pressure forcing the cerebro spinal fluid into the meningeal sheath which invests the optic nerve and into the perivascular spaces which accompany the central vessels of the nerve The nerve sheath becomes distended and venous stasis occurs On ophthalmoscopic examination the earliest changes are increased redness of the disk with disappearance of the physiological pit As the process increases the whole margin of the disk becomes lost It enlarges in area and becomes visibly swollen and presents the appearance of a mole hill as seen from above The point of emergence of the vessels at the centre of the disk becomes buried by white exudation which occurs also all over the disk and taking a form determined by the radiating nerve fibrils gives the disk the appearance of being striated in a radial fashion like a chrysanthemum A similar exudate may rupture the membrana limitans interna in little droplets at the macula and coagulating as it comes in contact with the vitreous humour produces the *characteristic radially* arranged macular figure or macular fan exactly similar to that seen in renal disease The venous congestion of the retina leads to multiple hæmorrhages which infiltrate along the radially arranged nerve fibres and for this reason are flame shaped With the outpouring of much exudation, the disk becomes white In the course of time the hæmorrhages become white flame shaped scars the whole disk contracts the swelling disappears and the disk becomes white flat and atrophic and distinguished only from that of primary optic atrophy by the scarred remains of the exudate at its edge producing a fluffy outline like that of torn cotton wool along the vessels and at the centre In the early stages of papillœdema even though there be considerable swelling of the disk vision is little impaired As the process increases however in proportion to the degree of the swelling to the amount of exudate and to the length of time the papillœdema has lasted consecutive optic atrophy sets in

any cause (5) Cysts following the breakdown of areas of the brain which have become necrotic from vascular occlusion (6) Cysts of the septum pellucidum (7) Colloid cysts of the third ventricle (8) Cysts derived from remnants of the developing pituitary body and described in connection with pituitary tumours (9) Dermoid cysts (10) Parasitic cysts of which the more common is the bladder worm of the tapeworm, tænia solium which is called on account of the thickness of its wall, cysticercus cellulosæ These are usually multiple, and grow in the folds of the pia mater in the depths of the sulci and occasionally in the fourth ventricle It is usual for these cysts to shrink and become calcified in from 3 to 6 years Less commonly the hydatid or cyst of tænia echinococcus is found It is usually single may reach a large size and present the signs of a slowly growing tumour with eosinophilia

INFECTIOUS GRANULOMATA —Tuberculomata are more common in the young but they may occur at any age They are secondary to tuberculosis elsewhere in the body They vary in size from that of a grain of wheat to that of a pigeon s egg and are more often found in the cerebellum and brain stem than in the cerebral hemispheres They may be solitary or multiple When large, caseation occurs in the centre and on section the tumour presents a dry yellowish crumbling or even diffluent centre with a greyish red peripheral growing zone where are located living tubercle bacilli and actively growing tubercles In old tuberculomata very dense calcification may take place with the formation of so called brain stones ' Before the advent of antibiotics the surgical removal of tuberculomata although readily carried out, was associated with so great a risk of fatal tuberculous meningitis that it was best avoided Now this risk can to a great extent be controlled and surgical removal is often the treatment of choice of chronic tuberculomata

Syphiloma is to day a very rare intracranial tumour It grows most often from the meninges and is thus a surface tumour though it may burrow deeply into the brain tissue It is most commonly found above the tentorium It is occasionally very hard in consistency and tends in many cases to scar and become obsolete It is sometimes impossible to distinguish this tumour from a tuberculoma without the aid of a microscope and the serum reaction Actinomycetoma and tumours from other streptothrix infections are also rare

Symptoms —The rates of growth of the different kinds of tumour vary widely Some cases run their course from onset of symptoms to fatal termination within a few weeks while in others there is evidence of gradual growth over a period of years In the latter group it may be only in the final stage that the true nature of the illness becomes apparent, and only in retrospect that earlier symptoms assume their real significance This is especially so in the case of those tumours which for months or years have manifested their presence only by generalised epileptiform fits In yet other cases an intracranial tumour may remain latent during life being revealed unexpectedly at post mortem examination

Between these two extremes a great variety of symptom complexes may be presented by an intracranial tumour Thus it may first show itself by producing signs of raised intracranial tension alone—that is by general signs or by signs of a gradually progressive *local* lesion alone—that is by *focal* signs *Whichever of these two elements* is initially lacking will probably appear later A third manner in which a tumour may first signal its existence is—as has been mentioned—by the occurrence of generalised epileptiform fits in the absence of any other symptoms and signs In this instance also general and focal signs will probably ultimately make their appearance Again a sudden onset of symptoms from hæmorrhage into a glioma or from œdema of surrounding brain may usher in the clinical course of a tumour within the skull

The age of the patient is not without influence in determining the symptomatology and clinical course of a tumour Thus in childhood the early appearance of greatly raised intracranial tension—that is of general symptoms is the rule This is mainly due to the fact that at this age the tumour is commonly in the fourth ventricle and

a slight heaviness and an absence of restlessness which is of value in diagnosis It is almost unheard of for a tumour patient to suffer from insomnia As the symptoms increase so do heaviness and drowsiness though a perfect but slow cerebration may persist until the latest stages of the disease

DIFFERENTIAL DIAGNOSIS OF TUMOURS IN THE PITUITARY REGION (WALSHE) (MODIFIED)

	Adenoma			Pituitary Stalk Tumour	Meningioma	Glioma of Optic Chiasma (rare)
	Chromophobe	Chromophil	Mixed Cell			
Age Incidence	From adolescence onwards			From 10 years to early adult life	From 30 years onwards	Usually in childhood
Fundus Oculi	Primary optic atrophy			Papillœdema in children usually primary optic atrophy in adults	Primary optic atrophy	Primary optic atrophy
Visual Fields	Bitemporal hemianopia (——Occasionally homonymous hemianopia——)			Bitemporal hemianopia or central scotomata	Bitemporal hemianopia	Bitemporal hemianopia proceeding to early blindness
Pressure Symptoms	Absent or late			Early and severe except in adults	Absent or late	Absent or late
Glandular Symptoms	Hypopituitarism	Hyperpituit or Hypopituit	Mixed	Hypopituitarism	Nil	Nil
Situation	Sellar			Suprasellar	Suprasellar	Suprasellar
Radiological	General enlargement and deepening of sella			Shadows above and in sella Sella shallow and with uneven floor	Commonly no change	Enlargement of sella forwards beneath ant clinoid processes

Double vision —Diplopia is a common symptom and is usually at first intermittent and experienced on looking to one or both sides It is due to weakness of one or both external rectus muscles and may be associated with an obvious convergent squint

vision becomes impaired and blindness results Peripheral constriction of the visual fields large pupil and dimness of vision are the signs that if the papillœdema be not speedily relieved blindness will certainly result Perfect vision may be retained for a time even with a high degree of papillœdema So important is papillœdema in the diagnosis of tumour of the brain that it is necessary to bear constantly in mind all other causes which may give rise to it

Papillœdema may occur in certain general intracranial conditions other than tumour (1) In meningitis as a late sign rarely before the tenth day and as many *cases of meningitis do not last so long it is chiefly met with in the less acute forms* such as tuberculous meningitis (2) States of arterial hypertension from whatever cause but particularly in malignant hypertension in young subjects (3) Renal disease may give a retinal picture of intense papillœdema macular figure and hæmorrhages sometimes quite indistinguishable from that due to tumour This is often seen in the small white kidney of young subjects and sometimes in small red kidney but there is no form of renal disease in which papillœdema has not been observed (4) Anæmic states of various kinds sometimes give rise to papillœdema As regards groups (3) and (4) it is essential to emphasise the facts that papillœdema headache and vomiting may occur as a symptom complex both in renal disease and in anæmic states (5) Septicæmic conditions especially infective endocarditis may *cause papillœdema (6) Lastly, papillœdema has been noted in connection* with compression of the uppermost part of the cervical cord and with acute myelitis

The retinal changes in diabetes are always and those in renal disease often distinguishable from papillœdema resulting from increased intracranial pressure *In* diabetes the change is essentially a hæmorrhagic retinitis due to degeneration of vessels sometimes with waxy looking exudation in circinate patches and in renal disease it is often a general œdema of papilla and retina with hæmorrhages and white patches far away from the disk The papillœdema resulting from increased intra cranial pressure is always bilateral though it may appear in one eye before the other unless there be local pressure upon one optic nerve which always delays or prevents papillœdema appearing in that eye Otherwise an earlier commencement upon one *side is of no localising value*

Headache —The sensation may vary from a mere feeling of fullness of the head to the most agonising pain It is more often remittent than continuous and may be absent for long periods together *it often occurs on first waking in the morning* or after a period of recumbency or stooping It is rarely localised to any definite region except when the growth actually involves the bone or when pressure has caused local thinning of the bone when local pain and tenderness on pressure may *occur* Usually it is referred indefinitely to the frontal or to the occipital or to the vertical region When occipital it may be associated with pain and stiffness of the neck and head retraction This is due to a general pressure effect and does not indicate any localisation Headache may be entirely absent even in the presence of severe papill œdema It may precede the development of papillœdema even by a long period or may be later in its appearance

Vomiting —Only two thirds of all cases of intracranial tumour present vomiting as a symptom It rarely occurs in the absence of the two chief signs of increased intracranial pressure papillœdema and headache When the headaches are severe it may be associated with much nausea and the attacks are often referred to by the *patient as* bilious attacks Usually a result of increased pressure it may be directly produced by lesions of the cerebellum irritation of the vestibular nerve and the visual disorientation resulting from diplopia As a symptom of intracranial tumour *it hardly deserves the* cardinal importance which has been assigned to it in most descriptions of this disease

Loss of vivacity and mental drowsiness —Even when intellectual capacity shows not the slightest *impairment there* is from the first onset of symptoms a loss of vivacity,

fields and will in addition give rise to dilated pupils inactive to light Less severe degrees of papillœdema may give rise to irregular constrictions of the fields of vision, which may easily be mistaken for an incomplete bitemporal or homonymous hemianopia When intracranial hypertension is severe particularly in the case of posterior fossa tumours a considerable degree of deafness may be present due to congestion of the structures of the internal ear on one or both sides

Proptosis is by no means uncommon in tumours of rapid growth or in the presence of rapidly developing internal hydrocephalus It is caused by venous congestion of the orbital contents and may be more marked on one side than on the other In women amenorrhœa may occur in cases with tumours elsewhere than in the neighbourhood of the pituitary body It is particularly common in mid cerebellar tumours causing severe hydrocephalus

Especial mention may be made of tumours of the pituitary body and stalk Their signs consist of a combination of endocrine disturbance and symptoms due to damage of surrounding nerve structures and have been described in a previous section but since the tumours in this neighbourhood have their own typical symptom complexes the table as shown on p 1387 may be useful in differentiating them

Diagnosis—The differential diagnosis of intracranial tumour has to be made from (1) other conditions causing papillœdema (2) other conditions causing headache and (3) other local lesions causing symptoms and signs of local diseases of the brain

Renal disease arterial hypertension cerebral syphilis and rarely encephalitis may be characterised by all three groups of symptoms and so present peculiar difficulty and should be considered in every case of suspected cerebral tumour Cerebral abscess is in a special category since it is a tumour in the wider sense of an expanding intracranial lesion and so shares all the general and local features of tumour Abscesses nearly always follow obvious suppuration elsewhere especially in the middle ear or nasal sinuses or in the thorax but they may be latent for long periods Their onset is insidious but usually more rapid than in the case of tumour and general signs such as low fever a toxic appearance and changes in the cerebro spinal fluid are present (see p 1405) Other causes of obstructive internal hydrocephalus may closely simulate tumour of these chronic arachnoiditis stenosis of the aqueduct of Sylvius and syphilitic or other forms of chronic basal meningitis may be mentioned Saccular aneurysms of the larger cerebral blood vessels may be mistaken for tumours with disastrous results

The diagnosis of intracranial tumour is not complete when a decision is reached that such a lesion is present within the skull it is necessary to localise its position and if possible to determine its nature This topographical and pathological diagnosis calls for a skilful evaluation of the various symptoms and signs against the background of the patient s history Careful examination of the skull should never be omitted This may reveal asymmetry of contour thickening of bone dilated blood vessels or areas of tenderness or altered percussion note which may give valuable information Auscultation may reveal an audible bruit In experienced hands this purely clinical approach gives results of considerable precision in many cases but there will always be a number of cases in which a complete diagnosis cannot be reached by purely clinical methods In the majority of these it will be evident that a tumour is present but the evidence will be insufficient to determine its position and nature In a minority a local lesion may be diagnosed with certainty but there may be doubt whether it is a tumour or some other destructive lesion In either case recourse has to be made to instrumental aid Radiographs of the skull may give valuable assistance These may show changes indicative of long standing increased intracranial pressure areas of local absorption of bone abnormal vascular channels or areas of abnormal calcification Examination of the cerebro spinal fluid may give valuable information but it should be practised with caution if there is reason to *suspect much increase in intracranial pressure* and should be avoided in the presence

Blood pressure, pulse rate and respiration—In many cases of intracranial tumour of slow growth these functions remain unaltered until the terminal stage of the disease, but in cases where there has been an excessive and rapid rise in intracranial pressure *e g* rapidly growing or degenerating tumours abscess, or extradural and subdural hæmorrhages they may be considerably altered Fall in the pulse rate is the most constant change and may reach figures around 40 per minute in a person with a normal rhythm of 70 to 80 per min Less common is a rise in blood pressure occurring *pari passu* with the fall in pulse rate It is most often seen in cases of rapid cerebral compression and is characteristic of extradural hæmorrhage Respiration tends to be slow and shallow and when cerebral compression is severe it is often irregular and may become grouped and may show the wax and wane of movements which bears the name of Cheyne Stokes respiration When the respiratory function is depressed the lips and extremities may be cyanosed—a sign of ill omen in tumour cases

Giddiness—This symptom is not infrequently reported by patients with intra cranial tumour particularly if it is situated below the tentorium It usually consists of a feeling of faintness and general unsteadiness particularly on stooping but may amount to true vertigo

Nasal irritation—This curious symptom is seen sufficiently often to make it worthy of mention The cause is quite unknown

Convulsions—As will be stressed later epileptic fits of all types indistinguish ble from those of idiopathic epilepsy are among the commonest early symptoms of tumours originating above the tentorium Much more rarely they may occur as a symptom of general increase in intracranial pressure particularly in young children and in cases where the increase of pressure has been very abrupt

FOCAL SIGNS—These have been fully described in the section upon the local isation of lesions of the brain but certain points require further emphasis Of all the early symptoms of tumours above the tentorium the most common is the occur rence of epileptic fits These may take the form of focal fits of any kind or may be generalised and may precede any other manifestation of intracranial tumour by many years Any person developing fits for the first time after the age of 25 should be looked upon as a tumour suspect Although in all cases of intracranial tumour the symptoms and signs of raised intracranial pressure ultimately make their appearance they may be late in doing so and in such cases the clinical picture is that of a pro gressive local destruction of brain tissue

In examining cases of intracranial tumour signs may be observed which appear to be conflicting or mutually contradictory In such it should be remembered that symptoms and signs which appear early in the clinical course are of greater localising value than those which appear late and that signs which only make their appearance in the presence of a severe rise in intracranial pressure should be treated with great reserve Of these so called false localising signs the most notorious is the abducens paresis seen in most cases of raised intracranial pressure It probably results from shifting of the brain stem and stretching of the nerve in its course through the sub arachnoid space and should always be disregarded as a localising sign To a less extent the same is true of the third fifth and seventh pairs of cranial nerves whose functions may show slight impairment in the presence of greatly increased pressure without any direct involvement of their fibres in the tumour On the other hand cranial nerve palsies occurring early in the course of the disease before there is any increase in intracranial tension may be valuable evidence of direct involvement of these nerves either in the brain stem or in their courses through the subarachnoid space or foramina of exit

The presence of papillœdema may considerably modify the localising informa tion to be obtained through the function of vision Blindness will naturally destroy all information which might have been obtained from an examination of the visual

is often justified But it would be a mistake to suppose that surgical intervention is a matter of routine in every case in which intracranial tumour is diagnosed Each case must be considered on its merits

Failing the possibility of a successful removal the palliative operation of decompression may be needed to relieve the symptoms caused by raised intracranial tension This consists of the free removal of bone and the incising of the dura mater over the region of the tumour For brain stem tumours decompression is not only useless but also dangerous

In cases in which complete removal has proved impossible deep X ray therapy may be employed The results are very variable Some types of tumour notably the medullablastoma respond very favourably at the time but usually recur after an interval which grows longer decade by decade as radiotherapeutic technique improves A survival period of 10 years or more is now not uncommon The response in the case of astrocytomas and glioblastomas is much less predictable but on the whole, is disappointing and when improvement occurs it is short lived

Relief of pressure by dehydration —There are circumstances in which it may be desirable and necessary to reduce the brain volume and the intracranial pressure, for example to relieve pressure headache to avert impending coma or death to render the patient capable of co operating in his examination and thus facilitating a localising diagnosis and finally to make surgical procedures more easy This may be achieved by administering hypertonic solutions In the ordinary case the rectal injection of from 2 to 3 oz of magnesium sulphate dissolved in 8 oz of water may be tried But for a very rapid effect intravenous injection of from 50 to 75 ml of a 50 per cent. solution of dextrose or sucrose or of a 15 per cent solution of sodium chloride is effective It should be remembered that when the effect of such medical decompression has worn off the symptoms of raised intracranial pressure are apt to reassert themselves with increased severity These methods should therefore only be employed with restraint when there is only a short time to be tided over before surgical relief is available Pain and vomiting may be relieved with the various analgesics of the coal tar series Morphine should not be used as it is followed by grave depression of respiration Codeine phosphate is a valuable analgesic which is relatively free from this disadvantage

MENINGITIS

Definition —The inflammatory processes to which we apply the name of meningitis are infective in origin and usually have their seat in the leptomeninges—the pia arachnoid A true inflammatory lesion of the dura mater that is pachymeningitis is much less common and is usually a localised process due to the direct spread of infection from adjacent bone

Acute leptomeningitis on the other hand is usually generalised and even when it arises from a local focus of infection it spreads rapidly throughout the subarachnoid space this spread being facilitated by the cerebro spinal fluid and also by the negligible bactericidal potency of this fluid Further the inflammation not only produces its characteristic changes in the pia arachnoid but also greatly changes the composition of the cerebro spinal fluid These changes may be said to reflect with considerable accuracy the nature and cause of the meningitis and thus it is that the examination of this fluid has so great a diagnostic value Acute leptomeningitis may result from invasion of the leptomeninges by organisms carried in the blood stream as occurs in septicæmic conditions meningococcal meningitis tuberculous meningitis and many cases of pneumococcal meningitis Alternatively the organism may reach the meninges by direct spread from a neighbouring focus of infection of which suppuration in the middle ear and nasal sinuses infections of the scalp skull face and eye and cerebral

of more than a trace of papillœdema Manometry may establish the presence or absence of raised intracranial pressure and analysis of the fluid may thro v important light upon the nature of the pathological process in the brain But the most important acce sory methods of diagnosis are ventriculography and angiography Ventriculo graphy is a purely surgical procedure and should only be carried out by an experienced neuro surgeon under circumstances in which it is possible to proceed forthwith to a major cerebral operation, if this should prove necessary By ventriculography, not only can the localisation of a tumour in many cases be established with accuracy but its extent can be defined, thus enabling the surgeon to plan his operation to the best advantage Further a number of cases can be demonstrated to be inoperable thus sparing the patient the discomfort of a fruitless exploration As experience and skill in ventriculography increase it becomes increasingly obvious that in very few cases can this investigation be wisely omitted before an attempt is made to remove a brain tumour Cerebral angiography by which radiographs of the cerebral blood vessels are taken while they are filled with an opaque substance has a more limited but increasing value in the investigation of tumours of the cerebral hemispheres and is now almost essential in cases of vascular tumours and suspected aneurysms In some cases the electro encephalogram may afford evidence of localising value

Course and Prognosis —An intracranial tumour usually causes increasing symp toms which progress with exacerbations and remissions until papillœdema ends in blindness and until the pathological intracranial condition becomes incompatible with even a vegetative existence Death usually comes in one of two ways More commonly the patient sinks gradually into stupor and from this into deepening coma in which he dies from hypostatic broncho pneumonia In a minority of cases death occurs suddenly by an abrupt cessation of respiration The patient becomes deeply cyanosed for the heart continues to beat for many minutes after respiration has failed and in such a condition the patient may be kept alive for hours by artificial respiration This mode of death is most common when the increase of intracranial pressure has been great and of rapid development as occurs in many posterior fossa tumours It is attributable to the failure of the medullary centres from the forcing of the cerebellum and brain stem down into the foramen magnum or from pressure exerted on the mid brain by herniation of the uncus through the incisura of the tentorium This accident may readily be precipitated by withdrawal of cerebro-spinal fluid by the lumbar route and it is for this reason that great caution should be exercised in performing this operation on patients with high intracranial pressure Occasionally a tumour may become obsolete A tuberculoma may heal and ulti mately become calcified and a glioma may degenerate or cease to grow, but these events are too rare to be considered within the bounds of practical perspective The average duration of cases not operated upon rarely exceeds a year after diagnosis has become certain

Treatment —The natural termination of a case of intracranial tumour is death and the ideal of treatment must be the successful removal of the growth by surgical operation Failing this and it is frequently impossible all that can be hoped for is the relief of headache and sickness and delaying of blindness

In respect of the radical surgical treatment of tumours it will be remembered that probably more than half of the cases (if we include glioma and secondary carci noma) are infiltrative tumours in the brain substance and thus not amenable to com plete removal In such it is clearly improper to carry out mutilating operations which can at best only serve to prolong for a time a life which is a burden both to the patient and his relatives On the other hand signal successes can be obtained in the case of meningiomas tumours of the auditory nerve and the pituitary body and some cystic astrocytomas particularly of the cerebellum It will therefore be seen how important it is to be able to determine with some precision the nature of the tumour present in any given case When this is not possible an exploratory operation

is often justified But it would be a mistake to suppose that surgical intervention is a matter of routine in every case in which intracranial tumour is diagnosed Each case must be considered on its merits

Failing the possibility of a successful removal the palliative operation of decompression may be needed to relieve the symptoms caused by raised intracranial tension This consists of the free removal of bone and the incising of the dura mater over the region of the tumour For brain stem tumours decompression is not only useless but also dangerous

In cases in which complete removal has proved impossible deep X ray therapy may be employed The results are very variable Some types of tumour notably the medullablastoma respond very favourably at the time but usually recur after an interval which grows longer decade by decade as radiotherapeutic technique improves A survival period of 10 years or more is now not uncommon The response in the case of astrocytomas and glioblastomas is much less predictable but on the whole is disappointing and when improvement occurs it is short lived

Relief of pressure by dehydration —There are circumstances in which it may be desirable and necessary to reduce the brain volume and the intracranial pressure for example to relieve pressure headache to avert impending coma or death to render the patient capable of co operating in his examination and thus facilitating a localising diagnosis and finally to make surgical procedures more easy This may be achieved by administering hypertonic solutions In the ordinary case the rectal injection of from 2 to 3 oz of magnesium sulphate dissolved in 8 oz of water may be tried But for a very rapid effect intravenous injection of from 50 to 75 ml of a 50 per cent solution of dextrose or sucrose or of a 15 per cent solution of sodium chloride is effective It should be remembered that when the effect of such medical decompression has worn off the symptoms of raised intracranial pressure are apt to reassert themselves with increased severity These methods should therefore only be employed with restraint when there is only a short time to be tided over before surgical relief is available Pain and vomiting may be relieved with the various analgesics of the coal tar series Morphine should not be used as it is followed by grave depression of respiration Codeine phosphate is a valuable analgesic which is relatively free from this disadvantage

MENINGITIS

Definition —The inflammatory processes to which we apply the name of meningitis are infective in origin and usually have their seat in the leptomeninges—the pia arachnoid A true inflammatory lesion of the dura mater that is pachymeningitis is much less common and is usually a localised process due to the direct spread of infection from adjacent bone

Acute leptomeningitis on the other hand is usually generalised and even when it arises from a local focus of infection it spreads rapidly throughout the subarachnoid space this spread being facilitated by the cerebro spinal fluid and also by the negligible bactericidal potency of this fluid Further the inflammation not only produces its characteristic changes in the pia arachnoid but also greatly changes the composition of the cerebro spinal fluid These changes may be said to reflect with considerable accuracy the nature and cause of the meningitis and thus it is that the examination of this fluid has so great a diagnostic value Acute leptomeningitis may result from invasion of the leptomeninges by organisms carried in the blood stream as occurs in septicæmic conditions meningococcal meningitis tuberculous meningitis and many cases of pneumococcal meningitis Alternatively the organism may reach the meninges by direct spread from a neighbouring focus of infection of which suppuration in the middle ear and nasal sinuses infections of the scalp skull face and eye and cerebral

abscesses are the most common It may also gain direct access by penetrating wounds of the head and as a complication of fracture of the base of the skull

Pachymeningitis may be cranial or spinal and is usually secondary to either syphilis tuberculous disease of bone or middle ear suppuration The condition *formerly known as* pachymeningitis hæmorrhagica interna is now regarded as traumatic and not inflammatory in origin, and is described under the heading of chronic subdural hæmatoma (see p 1450)

The fine infiltration of the pia arachnoid by the cells of secondary carcinoma of glioma or sarcoma has been spoken of as a meningitis but although such an infiltration may give rise *to symptoms resembling those of a true meningitis the term is* not strictly accurate, though it is well to bear in mind that this form of new growth does occur and give a picture of meningeal irritation

The most useful classification of the varieties of meningitis is according to the nature of the micro organism producing the inflammation namely (1) Meningococcal Meningitis (2) *Pneumococcal Meningitis* (3) *Pyogenic Meningitis*, (4) Tuberculous Meningitis (5) Benign Lymphocytic Meningitis, (6) Syphilitic Meningitis and (7) Other Forms of Meningitis

(1) MENINGOCOCCAL MENINGITIS (see p 54)

(2) PNEUMOCOCCAL MENINGITIS

Ætiology —Pneumococcal infection of the meninges most commonly follows upon a similar infection elsewhere in the body empyema and pneumococcal otitis being the commonest lesions while pneumonia abdominal infection abscess and joint infection are less common In one third of the cases however the meningeal infection is primary The characteristics of the cerebro spinal fluid are that it is purulent and sometimes so thick that it will not flow through the needle It is greenish yellow in colour, contains a large amount of albumin and multitudinous polymorphonuclear cells, among which the characteristic pneumococcus is found In fulminant rapidly fatal cases the fluid may be turbid from the presence of pneumococci alone *no reaction in the form of pleocytosis being present The disease may occur at any* age It is sometimes a terminal event of a pneumococcal infection elsewhere and passes almost unnoticed or is discovered only at the autopsy Meningitis which follows operations upon the nose and disease of the nasal bones is usually of the pneumococcal variety

Pathology —The surface of the brain and spinal cord is highly characteristic Usually the whole surface of the vertex and of the base is covered with a thick tenacious greenish yellow pus which is contained in the meshes of the arachnoid and between this and the dura The ventricles often contain pus A similar exudation is found upon the spinal cord more especially upon the dorsal aspect and in the cervical and lumbo sacral regions The major affection of the vertex of the brain is the peculiarity of this disease and only in the rarest cases is the base alone affected The exudation is characterised by a greater amount of fibrin than in other forms of meningitis

Symptoms —The symptoms are those which are common to all forms of meningitis Some of the cases are indistinguishable symptomatically from those of tuberculous meningitis *Others run a very rapid course and present few features other* than headache vomiting and pyrexia with a rapidly oncoming and quickly fatal coma In others again the meningeal symptoms are concealed in the terminal asthenia of a previously existing pneumococcal infection elsewhere such as empyema purulent pericarditis or peritonitis

Diagnosis —This rests upon the presence of signs of meningitis or the existence of coma alone together with a cerebrospinal fluid which is purulent from the presence of polymorphonuclear leucocytes and the finding of pneumococci in the fluid

Prognosis and Treatment —In the past pneumococcal meningitis was uniformly fatal Occasional recovery was later reported as a result of treatment with pneumo coccal antisera

The introduction of sulphonamide therapy led to a marked improvement in the outlook and the use of penicillin has completely changed the prognosis in this grave disorder in which the mortality should not now be more than 10 to 20 per cent if treatment is initiated immediately According to Honor Smith and her co workers penicillin should be administered intrathecally by the lumbar route in doses of 8000 to 16 000 units 12 hourly for the first 2 days and thereafter 24 hourly for a further 3 days This should be combined with intramuscular administration of 120 000 units of penicillin daily and with sulphadiazine by mouth an initial dose of 4 g being followed by 2 g 4 hourly for several days after the fever has settled Adverse re actions have been reported in cases where more than 20 000 units of penicillin were administered intrathecally in one dose Blockage of the cerebral or spinal subarachnoid space by the accumulation of organising purulent lymph may necessitate the giving of penicillin by the cisternal or ventricular routes

More recently favourable results have followed the use of penicillin alone in massive doses intramuscularly 2 000 000 units every 2 hours, none being given intrathecally

(3) PYOGENIC MENINGITIS

Apart from meningococcal and pneumococcal infections suppurative meningitis may result from the invasion of the meninges by staphylococci streptococci gono cocci *H influenzæ* coliform bacilli *B anthracis* and streptothrix

Staphylococcal and streptococcal infections are by far the most common They may result in young children from septic conditions of the umbilicus and from infec tions of the skin Usually they are due to extension of an infection from structures adjacent to the meninges and follow disease of cranial and spinal bones, especially caries in the middle ear erysipelas and other infections of the scalp wounds of the meninges especially bullet wounds rupture of intracranial abscess and they may occur in the course of a general septicæmia

Pathology —The pathology of these conditions does not materially differ from that of pneumococcal meningitis In all cases the exudation is purulent and in the meningitis due to *B anthracis* it is of a red colour due to concomitant blood effusion The cerebro spinal fluid contains large numbers of polymorphonuclear leucocytes together with the micro organism responsible for each variety Suppurative menin gitis resulting from bone disease and from wounds of the meninges may be localised by the formation of meningeal adhesions and an intrameningeal abscess may result Such an abscess situated upon the upper surface of the temporal bone is not an uncommon result of caries of the middle ear

The clinical aspect is that common to all forms of acute meningitis high pyrexia rigors and delirium being conspicuous The course is rapid and before the intro duction of modern chemotherapy led to an almost invariably fatal termination In the localised form where drainage can be ensured and extension of the infection prevented recovery should take place

Diagnosis —This depends upon the presence of the clinical signs of meningitis and of a cerebro spinal fluid containing polymorphonuclear leucocytes in large quanti ties and upon the recognition in this fluid of the several micro organisms responsible by microscopic examination and culture The recognition of *H influenzæ* requires that cultures should be made upon a blood medium for otherwise the organism may be easily overlooked and the fluid reported as sterile Further the presence of some well known cause for suppurative meningitis such as ear disease staphylococcal infection etc suggests the diagnosis

Acute otitis media may give rise to symptoms closely resembling those of meningitis such as headache pyrexia vomiting head retraction and delirium In such cases examination of the ear which should be made a routine in all cases where meningitis is suspected will reveal tympanic distension the relief of which is followed by a speedy disappearance of the symptoms In this connection it must be borne in mind that meningitis and intracranial abscess seldom follow directly upon acute otitis but are usually the sequelæ of chronic otitis which has resulted in caries of the temporal bone When evidences of caries of the middle ear are present in a case presenting cerebral symptoms distinction has to be made between meningitis and abscess of the brain Here the presence of localising symptoms either temporal or cerebellar and the presence of papillœdema and any tendency to a temporary abatement of the symptoms point to the existence of an abscess and further lumbar puncture will in all but the rarest cases settle the point In cases of abscess in which cells and organisms are found in the cerebrospinal fluid these exist in small numbers only as compared with the copious cells and organisms present in the fluid of suppurative meningitis (see p 1409)

Treatment —In cases of meningitis secondary to mastoid disease the source of infection should be at once cleared out by surgical procedure As in the case of pneumococcal meningitis the prognosis and treatment of all forms of pyogenic meningitis have been profoundly altered by the introduction of sulphanilamide and its derivatives and of antibiotics and the treatment in general is the same as that which has already been described in the case of pneumococcal meningitis Meningitis due to *H influenzæ Ps pyocyanea* and to some strains of coliform bacilli has been shown to respond favourably to treatment with streptomycin and other antibiotics (see pp 10 and 13)

(4) TUBERCULOUS MENINGITIS

This disease results from the general invasion of the cerebro spinal leptomeninges by the tubercle bacillus and this organism invariably arrives in the meninges by the blood stream from some previously existing focus of tuberculous infection elsewhere and most commonly from caseous tracheo bronchial and mesenteric glands and tuberculous bone disease Occurring at all ages it is the form by far the most frequently met with in the second and third years of life

Ætiology —Tuberculous meningitis is rare during the first year of life and especially during the first 6 months Its greatest incidence is during the second and third years It is common throughout childhood and early adult life, after which it becomes increasingly rare though cases may be met with even in the elderly The sexes are equally affected The primary focus from which the organisms are carried to the meninges is most often a tuberculous bronchial or mesenteric lymph gland In consequence the most potent causes of the disease are exposure of the young child to cases of open tuberculosis and the drinking of infected milk

Sometimes the source of infection is tuberculous disease of the lungs of the uro genital tract of the abdomen of the ear of the joints or of bone Operations upon the sites of tuberculous disease may directly cause the dissemination of the tubercle bacilli and especially surgical procedures upon tuberculous intracranial tumours upon spinal caries and upon tuberculous disease of bones and joints The acute specific fevers and especially measles are sometimes the exciting causes of the disease Injury to the head sometimes determines the attack

Pathology —The essential change in tuberculous meningitis is the presence of an inflammatory exudate studded with discrete miliary tubercles in the pia arachnoid membranes particularly in the interpeduncular space and over the base of the brain

On removing the skull cap the dura is found to be so tense that it can only with difficulty be indented by the pressure of a finger When the dura is incised the cerebral convolutions are seen to be flattened and pressed firmly against the inner

surface of the dura No cerebrospinal fluid escapes from over the surface of the hemispheres In extracting the brain from the skull it is commonly ruptured and fluid escapes with a gush from the dilated ventricular system allowing the hemispheres to collapse The base of the brain especially the interpeduncular space is seen to be covered with a gelatinous greenish yellow exudate which surrounds the optic chiasma the emerging cranial nerves and infundibulum and the vessels of the circle of Willis and spreads out to the tips of the temporal lobes and to the stems of the Sylvian fissures Only rarely does this exudate spread on to the convex surfaces of the brain In cases of relatively long duration the exudate acquires a greyish colour and is tough in consistency and firmly adherent to the brain Close inspection of this inflammatory exudate shows it to be studded with innumerable small grey tubercles These are particularly numerous in relation to the blood vessels and they can be seen in large numbers along the course of the middle and anterior cerebral arteries The whole ventricular system is uniformly and greatly dilated and flakes of green gelatinous lymph may be found mixed with the cerebrospinal fluid contained in the distended ventricles Frequently small tubercles can be seen scattered over the walls of the ventricles and over the surface of the choroid plexuses Not infrequently discrete tuberculous foci may be found scattered through the substance of the hemispheres cerebellum and brain stem These vary in size from the pin point tubercles characteristic of the basal meninges to caseating masses the size of a marble Rarely thrombosis may be seen in one or other of the venous sinuses and occasionally areas of softening are found in the brain substances

The meninges of the spinal cord are usually also involved and tubercles may be seen upon the surface of the cord or the inner aspect of the dura mater

Examination of the rest of the body almost invariably shows the changes of general ised miliary tuberculosis the exception being those rare cases in which tuberculous meningitis has resulted from a tuberculoma in the substance of the brain

Symptoms —The onset is usually gradual with signs of vague and slight illness In children general apathy and neglect of amusements and play headache loss of appetite obstinate constipation dullness fretfulness restlessness at night with grind ing of the teeth during sleep headache vomiting and pyrexia are common symptoms In older subjects lassitude depression mental alteration perversity and hysterical manifestations are frequent Constipation is usually present and the breath has a peculiar fetor The facial expression is one of illness and frowning discomfort and there is disinclination to talk Young children may be speechless for days together As a rule in this stage of the disease young children complain of nothing and delirium is rare but as age advances delirium increases in frequency and headache usually frontal is increasingly complained of These slight and vague symptoms may last from a few days to several weeks and constitute what has been called the prodromal stage of the malady An early disappearance of the knee and ankle jerks and the occurrence of retention of urine are often early signs and should be looked for in suspected cases In those cases which are said to begin acutely careful enquiry will generally reveal that some symptoms such as the above have preceded the acute onset The further development of the disease is marked by the appearance of a lethargy which soon deepens into a stupor from which it is difficult or impossible to arouse the patient Vomiting is of frequent occurrence and headache may be severe The child lies upon its side in a cramped position resenting any disturbance The expression becomes vacant with wide open eyes and dilated pupils as if the gaze were fixed upon some distant object There is often some retraction of the angles of the mouth and there is frequently a bright malar flush In the later stages the limbs are generally extended and rigid Stiffness of the neck is the rule and head retraction may occur but this is never so marked as in pyogenic meningitis The abdomen is always markedly retracted and a tache cerebrale is often conspicuous A single sharp cry apparently causeless called the hydrocephalic cry which is common in all

forms of meningitis and also in other infantile intracranial affections is sometimes heard

Ocular phenomena make their appearance towards the end of the first week of the developed disease All varieties of varying and persistent strabismus and ptosis are met with paralysis of the external rectus being the most common Rolling movements and independent movements of the eyeballs may occur None of these signs is constantly present The pupils may be contracted at first and may show varying inequality but in the later stages they are dilated Papilloedema is often present *towards the end of the second week if the patient survives so long It is of moderate* intensity the height of the swelling rarely exceeding two dioptres Choroidal tubercles sometimes occur

Convulsions are common in every stage of the disease in children but rare in adult cases They may be the first symptom of the onset but are more often met with in the later stages of the disease They may be local or general Repeated rhythmic movements are frequent and are specially noticeable in connection with the mouth where sucking and champing movements and grinding of the teeth are common Rhythmic movements of the limbs may also occur Coarse tremor upon movement of the limbs is the rule, and spasmodic twitching of the muscles is frequent In rare cases, movements exactly like those of chorea occur Kernig s sign is usually present

The temperature is usually raised one or two degrees but it presents no characteristic features Irregularity of the pulse is the rule and is of considerable diagnostic importance Rapid in the early stages it tends to become unduly slow in the stage of coma and again rapid as death nears Cheyne Stokes breathing and grouped breathing are common Constipation is usually a marked and persistent feature

Diagnosis—The early symptoms of the disease may give rise to difficulty in diagnosis but this is relatively simple when the disease is advanced The diseases liable to be confused with tuberculous meningitis at its commencement are other forms of meningitis virus diseases of the nervous system especially acute poliomyelitis cerebral abscess the exanthemata—especially enteric fever—and pneumonia It must be borne in mind that in children convulsion strabismus head retraction and stiffness of the neck with pyrexia may be symptomatic of many maladies apart from meningitis especially of apical pneumonia When signs of meningeal irritation are unmistakable the condition has to be distinguished from the various forms of pyogenic meningitis In the latter the degree of meningism is usually more intense and the cerebrospinal fluid reveals a turbid or purulent fluid with a predominantly polymorph pleocytosis and the causative organism can usually be cultured

Poliomyelitis and other virus infections of the nervous system can at their commencement closely simulate tuberculous meningitis and it is in such cases that the retention of the cerebrospinal fluid chlorides and glucose at their normal level can be such a valuable aid to diagnosis

The meningeal reaction apt to arise from time to time in cases of cerebral abscess may closely resemble tuberculous meningitis and may be associated with a mixed pleocytosis and a sterile fluid

In any case suspected of being one of tuberculous meningitis a diagnostic lumbar puncture should be carried out without delay as the success of modern treatment is much influenced by the time of its commencement The characteristic features of the fluid are that it is usually under considerable pressure it is clear or only slightly turbid, has no visible deposit before centrifugalisation but it often forms a fine flocculent clot It contains an excess of albumin The normal sugar is reduced or absent and a value over 50 mg per 100 ml practically excludes the diagnosis It is sometimes between 40 and 50 mg per 100 ml but in the majority values under 30 mg are obtained In other forms of non purulent meningitis such a poliomyelitis and benign *lymphocytic meningitis the glucose content of the cerebrospinal fluid is*

almost invariably normal Early reduction of the chloride content below 700 or even 650 mg per cent is of value in distinguishing tuberculous meningitis especially from virus diseases of the nervous system There is a pleocytosis with a high proportion of lymphocytes 70 to 80 per cent being of this nature and the rest being polymorphonuclears Careful examination will reveal the presence of the tubercle bacillus in more than half the cases and their presence can be readily demonstrated by injecting the fluid into the subcutaneous tissue of guinea pigs when the characteristic lesion of tubercle results and also by culture It must be remembered that in some cases the polymorphonuclear leucocytes may be in excess but these cases are at once distinguished from other forms of meningitis by the presence of numerous lymphocytes by the absence of the meningococcus and of the other pyogenic organisms and by the presence of the tubercle bacillus

Course and Treatment —Before the advent of streptomycin tuberculous meningitis was invariably fatal and usually ended in the patient s death in from 3 to 8 weeks of the onset of symptoms

To day provided that early diagnosis is achieved the vigorous use of streptomycin together with sodium aminosalicylate (P A S) and isoniazid (I N H) should result in recovery in at least 50 per cent of cases

Streptomycin is administered both intrathecally and intramuscularly and either sodium aminosalicylate or isoniazid by mouth continuously for the initial period of 8 to 12 weeks If general improvement as measured by appetite weight subsidence of fever and loss of drowsiness is satisfactory and is confirmed by a gradual return of the cerebrospinal fluid towards normal a rest of 1 month in intrathecal treatment alone should be given At the end of this period a further course should be given and thereafter a gradual withdrawal of treatment may be achieved provided always that improvement is maintained Good results are now being obtained using isoniazid (*e g* 100 mg t d s) combined with streptomycin administered only by the intra muscular route (*e g* 1 g daily) thereby avoiding the need for daily intrathecal injections The addition of cortisone to this regime is still *sub judice*

Careful observation at increasing intervals must be maintained over a period of 5 years

Prominent among the complications which may arise are chronic hydrocephalus from the development of a plastic meningeal fibrosis around the base of the brain and leading in its turn to double hemiplegia convulsions blindness and imbecility and deafness from the degeneration in the cochlear nerves resulting from the use of intra thecal streptomycin

(5) BENIGN LYMPHOCYTIC MENINGITIS (CHORIO MENINGITIS)

Synonyms —Epidemic Serous Meningitis Benign Aseptic Meningitis

Ætiology —The causative agent is unknown but there is evidence that one or more neurotropic viruses are responsible No organisms have been found in the cerebro spinal fluid The disease has been transmitted to animals by injection of cerebro spinal fluid obtained in the acute stage of the affection The malady so named appears to be of wide distribution

Pathology —Since recovery is the rule nothing much is known of this but lymphocytic infiltration of the lepto meninges has been found in one fatal case

Symptoms —Children are mostly affected but no age appears exempt The onset is abrupt with headache sickness and fever The typical signs of meningeal irritation are present neck and spine rigidity Kernig s sign irritability and restlessness and sometimes delirium Somnolence is unusual In young children convulsions may occur The fever mounts to 102 or 103 F and fluctuates It may disappear in 2 or 3 days or persist for 3 weeks Lumbar puncture yields a cerebrospinal fluid under pressure usually clear but sometimes opalescent The cell count ranges from

50 to 1500 per c mm After the first 2 or 3 days these cells are almost wholly lymphocytes The sugar and chloride contents remain at normal height thus differing from the findings in other forms of acute lepto meningitis, and resembling the findings in acute poliomyelitis

Diagnosis —This depends upon the cerebrospinal fluid findings and upon the benign course of the illness For a few days differentiation from poliomyelitis may be impossible

Prognosis —Recovery is the rule

Treatment —Repeated lumbar puncture reduces the intracranial tension Beyond this only general nursing care is needed

(6) SYPHILITIC MENINGITIS

Meningitis due to infection by *Treponema pallidum* is one of the characteristic lesions met with in practically all cases of syphilitic disease of the central nervous system and plays its part in the production of the symptom complexes of these maladies from acute cerebral syphilis and acute myelitis to general paralysis and locomotor ataxy It may occur at any period after infection, but one half of the cases occur during the first 4 years In a few cases the symptoms have been noticed co incidently with the syphilitic roseola

Pathology —The morbid process consists essentially in an infiltration of the meninges with lymphocytes and plasma cells spreading from the perivascular spaces where the spirochætes multiply freely, and it may lead to scarring and opacity of the membranes with consequent strangling of the nerves and vessels and occlusion of the arachnoid space or to massive gummatous formation in the meninges It is essentially a chronic form of meningitis though it may result in the production of acute symptoms A marked feature is that the meningeal changes may be found actively progressive in one spot and equally regressive in another The disease may be local or diffuse and it may attack the dura (pachymeningitis) and involve the over lying bone or it may spread from the pia arachnoid into the sublying nervous tissue (meningo encephalitis)

The cerebrospinal fluid is characteristic It is usually under increased pressure is clear and colourless and contains lymphocytes and no other cell forms The number of the lymphocytes present is in direct proportion to the activity of the meningeal syphilis The spirochæte has rarely been found in the fluid yet inoculation of apes with the fluid has proved successful

Symptoms —Apart from those conditions of nervous syphilis in which meningitis is associated with arterial disease the formation of massive gummata and neuronic degeneration syphilitic meningitis may be described as giving rise clinically to the following conditions

1 *Headache*

2 *Hydrocephalus* —In those acute cases of cerebral syphilis characterised by rapidly oncoming headache, vomiting and papillœdema mental reduction and somnol ence without localising symptoms and which respond readily to treatment, it seems certain that ventricular distension, consequent upon adhesive meningitis and ependy mitis is responsible A more slowly oncoming ventricular occlusion may give rise to symptoms which cannot be distinguished from those caused by a non localisable intracranial tumour Syphilitic meningeal occlusion may give rise to typical hydro cephalus and a considerable proportion of the cases of infantile hydrocephalus are of this nature and are due to congenital syphilis A few cases are recorded in which chronic hydrocephalus of this nature has occurred in adult life

3 *Infantile syphilitic meningitis* —This is a chronic malady which commences insidiously during the first few months of life with signs of general nervous deteriora tion The appearance of the brain is very characteristic The membrane over the

vertex is opaque and thickened and adherent to the cortex The gyri are shrunken the sulci wide and the surface of the brain has in parts the appearance of wash leather The child does not get on and takes an ever decreasing notice of its surroundings Power of movement lessens the limbs become rigid and the clinical aspect comes to resemble exactly that of a severe cerebral diplegia Convulsions are of frequent occurrence The diagnosis is not difficult for the signs of meningitis are obvious and those of congenital syphilis may be present There is an excess of lymphocytes in the cerebrospinal fluid both in which and in the blood there is a positive Wassermann reaction The prognosis in any case where the symptoms have become marked is most unfavourable

4 *Adult syphilitic meningitis* with a symptom complex closely resembling that of tuberculous meningitis has been reported on many occasions (see pp 1395 1461)

5 *Paralysis of cranial nerves*—This common and often isolated symptom of nervous syphilis may result from sclerosing basal meningitis or from the presence of a gumma in the course of the nerve Several of the nerves may be involved together in one patch of meningitis Any of the cranial nerves may be affected from the olfactory to the hypoglossal but the third or oculo motor nerve is by far the most frequently attacked

Treatment—The treatment of the above conditions is that appropriate for nervous syphilis in general (pp 223 1461) Penicillin is now the treatment of choice but a diminishing number of physicians still prefer to follow it up with courses of bismuth and organic arsenic by injection Iodide of potassium is also of value and should be administered over a long period

MENINGISM

The term meningism is used for a group of cases which present symptoms of meningitis and in which no pathological change can be found either in the cerebro spinal fluid or if death occur in the meninges or cerebral tissue It is met with in children in association with acute febrile diseases and is presumably due to the toxin present Recovery is usually rapid and complete

HYDROCEPHALUS

Definition—The term hydrocephalus denotes an abnormal accumulation of cerebrospinal fluid within the skull This may be confined to the ventricular cavities giving rise to the variety known as internal hydrocephalus or it may involve both the ventricular and the general subarachnoid spaces a condition referred to as communicating hydrocephalus This distension is associated in many cases with an expansion of the cranial bones and enlargement of the skull

General Considerations—Theoretically this abnormal increase of fluid may result from one or more of three causes viz (1) excessive production of fluid (2) interference in the normal flow of fluid and (3) defective absorption The fluid is normally produced by the choroid plexuses of the ventricles and flows through the ventricular system into the general subarachnoid space by way of the foramina of Luschka and Magendie in the roof of the fourth ventricle It then fills the basal cisterns and passing forward between the tentorium cerebelli and the brain stem flows up over the cerebral hemispheres to be absorbed by the arachnoid villi which project into the walls of the venous sinuses and discharge their contents into the venous blood stream Some of the fluid passes downwards into the spinal subarachnoid space but it is estimated that only one tenth of the fluid is absorbed from arachnoid villi in the spinal spaces

Of the causes of hydrocephalus the most important and the one of which we have the most precise knowledge is obstruction of the normal cerebrospinal flow and it

is evident that this obstruction may occur at several different points and be produced by a great variety of pathological causes Some of these are known and some remain obscure It will thus be seen that hydrocephalus is the end result of a variety of causes and until our knowledge is more complete it is most satisfactorily classified on a clinical basis and described as a number of clinical pictures which recur with some frequency

The following principal varieties of hydrocephalus are met with (1) congenital hydrocephalus, (2) chronic acquired hydrocephalus and (3) acute acquired hydrocephalus

In the majority of cases in which general atrophy of the cerebral tissues occurs fluid accumulates both in the ventricles and in the subarachnoid space but such compensating enlargement is not to be regarded as in any sense of the same nature as true hydrocephalus Such accumulation of fluid is found in cases of cerebral diplegia general paralysis of the insane cerebral arteriosclerosis and chronic alcoholism and it also occurs in the brains of old people It is merely the result of wasting and shrinkage of the brain tissue and the accumulation of fluid takes place in order to fill the space within the rigid skull which is thus vacated

(1) CONGENITAL HYDROCEPHALUS

Ætiology—Hereditary influences are of importance in the causation of congenital hydrocephalus This disease frequently affects several children of the same parents and it may even appear as a striking familial disease affecting members of several generations of the same stock Spina bifida meningocele and hydromyelia are of frequent occurrence in association with this condition and irregular or arrested development of the brain stem and cerebellum particularly the Arnaldo Chiari malformation are common Among other bodily abnormalities not infrequently associated with the affection may be mentioned hare lip cleft palate talipes rectal and testicular ectopia and imperforate anus In a few cases definite syphilitic lesions of the ependyma of the brain stem in the region of the aqueduct or fourth ventricle have been found In many cases the ætiology remains completely unknown

Pathology—The quantity of fluid which is found in the ventricles after death varies greatly usually being 15 to 20 oz In long standing cases with great cranial enlargement very large quantities have been met with The character of the fluid does not usually greatly differ from that of normal cerebrospinal fluid Its specific gravity varies from 1 008 to 1 010 It is clear and colourless or occasionally slightly yellow It contains a very small quantity of albumin and a normal quantity of chlorides The dilatation of the lateral ventricles is more extensive than that of the third and fourth ventricles and is usually symmetrical upon the two sides *It affects the* body more than the cornua of the ventricles so that the central cortex is most thinned The foramina of Monro are greatly enlarged and the anterior pillars wasted The convolutions are flattened and the sulci indistinct The thickness of the cerebral substance is much reduced In advanced cases the cerebral hemispheres have the appearance of thin walled sacs which collapse entirely when the contained fluid is allowed to escape In a few cases the aqueduct has been found closed as if by an antecedent ependymitis

Symptoms—In congenital hydrocephalus the enlargement of the head is the first noticeable feature It may take place during intra uterine life and it may be so great as to make delivery impossible without destruction of the head More frequently the cranial enlargement not noted at the time of birth becomes evident during the first weeks of life The increase usually affects all the diameters of the cranial cavity and is most marked at the vertex and least at the base Trousseau compared the opening out of the cranial bones, which occurs as the head enlarges to the falling back of the petals of an opening flower The forehead is large rounded,

and projects forward the temporal fossæ are obliterated and the parietal eminences carried backwards The vertex is often somewhat flattened as also may be the occipital region The direction of the external auditory meatus alters with the increasing size of the head normally directed obliquely forwards it comes to look directly inwards or even obliquely backwards in severe cases The head is frequently asymmetrical The sutures may be widely open and then there is marked bulging along these lines and at the fontanelles The skull may attain enormous dimensions, and it may be beyond the child s power to lift or even move the head Many examples are recorded in which the circumference has been from 60 to 80 cm The face is characteristically triangular contrasting markedly with the forehead Wasting of the facial subcutaneous tissues and retarded development of the maxilla and mandible often render the contrast still more striking Bulging of the orbital plates of the frontal bones presses down the eyeballs so that the pupils become more or less covered by the lower lids and a band of the sclerotic may be visible between the iris and the upper lid The hydrocephalic child often uses his hands to depress the cheeks and so draws down the lower lids out of the position which they impair the line of vision The hair of the head becomes scanty the subcutaneous veins of the scalp are often greatly developed and distended ands ometimes a vortex of dis tended veins radiates from the region of the anterior fontanelle Percussion of the skull gives a characteristic hollow cracked pot note

The general nutrition is poor and bodily development retarded in proportion to the severity of the effect of the hydrocephalus upon the nervous system The nervous symptoms which appear during the course of congenital hydrocephalus are both variable and inconstant depending upon the severity of the condition and the rate at which it progresses They may be summed up in the following list in order of frequency convulsions mental failure spastic paralysis of the limbs optic atrophy deafness nystagmus headache papillœdema and vomiting There is no constancy regarding these symptoms Convulsions may be absent and mental acuity may be unimpaired Spastic weakness occurs in less than half the cases optic atrophy still more rarely and papillœdema is distinctly unusual

Convulsion —While it is to be borne in mind that the whole course of hydro cephalus in children may run without the occurrence of convulsion yet in the majority of cases this symptom is conspicuous In some of the post natal cases the symptoms of cerebral disorder are ushered in by convulsion and it is probable that in many cases such convulsions are the immediate expressions of the morbid process of which the primary hydrocephalus is the final result The convulsions which recur at intervals throughout the course of the majority of cases of hydrocephalus result from a condi tion of functional instability of the cerebral cortex which long continued increased intracranial pressure brings about The convulsions are usually general with loss of consciousness

Mental impairment —All degrees of mental reduction occur from the least notice able to complete idiocy The more severe forms are met with in cases when cerebral agenesia and porencephaly are associated The psychical reduction is less prominent the greater the age at which the symptoms commence and as a rule the intelligence is far greater than the severity of symptoms (cranial enlargement paresis etc) might lead one to expect Cerebration is usually slow and the disposition placid and periods of somnolence are of common occurrence

Paralysis —The effect of long continued ventricular distension in many cases is to cause degeneration of the pyramidal system and according to its degree the latter entails bilateral spastic paralysis with contracture The first signs of the onset of this event are exaggeration of the deep reflexes and the change in type of the plantar reflexes from the flexor to the extensor response The lower extremities are affected earlier and to a greater extent than are the upper and at one period of the disease a case may present the picture of cerebral diplegic rigidity comparable with that of

is evident that this obstruction may occur at several different points and be produced by a great variety of pathological causes Some of these are known and some remain obscure It will thus be seen that hydrocephalus is the end result of a variety of causes and until our knowledge is more complete, it is most satisfactorily classified on a clinical basis and described as a number of clinical pictures which recur with some frequency

The following principal varieties of hydrocephalus are met with (1) congenital hydrocephalus (2) chronic acquired hydrocephalus and (3) acute acquired hydrocephalus

In the majority of cases in which general atrophy of the cerebral tissues occurs fluid accumulates both in the ventricles and in the subarachnoid space but such compensating enlargement is not to be regarded as in any sense, of the same nature as true hydrocephalus Such accumulation of fluid is found in cases of cerebral diplegia general paralysis of the insane cerebral arteriosclerosis and chronic alcoholism and it also occurs in the brains of old people It is merely the result of wasting and shrinkage of the brain tissue, and the accumulation of fluid takes place in order to fill the space within the rigid skull which is thus vacated

(1) CONGENITAL HYDROCEPHALUS

Ætiology —Hereditary influences are of importance in the causation of congenital hydrocephalus This disease frequently affects several children of the same parents and it may even appear as a striking familial disease affecting members of several generations of the same stock Spina bifida meningocele and hydromyelia are of frequent occurrence in association with this condition and irregular or arrested development of the brain stem and cerebellum particularly the Arnaldo Chiari malformation are common Among other bodily abnormalities not infrequently associated with the affection may be mentioned hare lip cleft palate, talipes rectal and testicular ectopia and imperforate anus In a few cases definite syphilitic lesions of the ependyma of the brain stem in the region of the aqueduct or fourth ventricle have been found In many cases the ætiology remains completely unknown

Pathology —The quantity of fluid which is found in the ventricles after death varies greatly usually being 15 to 20 oz In long standing cases with great cranial enlargement very large quantities have been met with The character of the fluid does not usually greatly differ from that of normal cerebrospinal fluid Its specific gravity varies from 1 008 to 1 010 It is clear and colourless or occasionally slightly yellow It contains a very small quantity of albumin and a normal quantity of chlorides The dilatation of the lateral ventricles is more extensive than that of the third and fourth ventricles and is usually symmetrical upon the two sides It affects the body more than the cornua of the ventricles so that the central cortex is most thinned The foramina of Monro are greatly enlarged and the anterior pillars wasted The convolutions are flattened and the sulci indistinct The thickness of the cerebral substance is much reduced In advanced cases the cerebral hemispheres have the appearance of thin walled sacs which collapse entirely when the contained fluid is allowed to escape In a few cases the aqueduct has been found closed as if by an antecedent ependymitis

Symptoms —In congenital hydrocephalus the enlargement of the head is the first noticeable feature It may take place during intra uterine life and it may be so great as to make delivery impossible without destruction of the head More frequently the cranial enlargement not noted at the time of birth, becomes evident during the first weeks of life The increase usually affects all the diameters of the cranial cavity and is most marked at the vertex and least at the base Trousseau compared the opening out of the cranial bones which occurs as the head enlarges to the falling back of the petals of an opening flower The forehead is large rounded

and projects forward the temporal fossæ are obliterated and the parietal eminences carried backwards The vertex is often somewhat flattened as also may be the occipital region The direction of the external auditory meatus alters with the increasing size of the head normally directed obliquely forwards it comes to look directly inwards or even obliquely backwards in severe cases The head is frequently asymmetrical The sutures may be widely open and then there is marked bulging along these lines and at the fontanelles The skull may attain enormous dimensions and it may be beyond the child s power to lift or even move the head Many examples are recorded in which the circumference has been from 60 to 80 cm The face is characteristically triangular contrasting markedly with the forehead Wasting of the facial subcutaneous tissues and retarded development of the maxilla and mandible often render the contrast still more striking Bulging of the orbital plates of the frontal bones presses down the eyeballs so that the pupils become more or less covered by the lower lids and a band of the sclerotic may be visible between the iris and the upper lid The hydrocephalic child often uses his hands to depress the cheeks and so draws down the lower lids out of the position which they impair the line of vision The hair of the head becomes scanty the subcutaneous veins of the scalp are often greatly developed and distended and sometimes a vortex of distended veins radiates from the region of the anterior fontanelle Percussion of the skull gives a characteristic hollow cracked pot note

The general nutrition is poor, and bodily development retarded in proportion to the severity of the effect of the hydrocephalus upon the nervous system The nervous symptoms which appear during the course of congenital hydrocephalus are both variable and inconstant depending upon the severity of the condition and the rate at which it progresses They may be summed up in the following list in order of frequency convulsions mental failure spastic paralysis of the limbs optic atrophy deafness nystagmus headache papillœdema and vomiting There is no constancy regarding these symptoms Convulsions may be absent and mental acuity may be unimpaired Spastic weakness occurs in less than half the cases optic atrophy still more rarely and papillœdema is distinctly unusual

Convulsion —While it is to be borne in mind that the whole course of hydrocephalus in children may run without the occurrence of convulsion yet in the majority of cases this symptom is conspicuous In some of the post natal cases the symptoms *of cerebral disorder are ushered in by convulsion and it is probable that in many* cases such convulsions are the immediate expressions of the morbid process of which the primary hydrocephalus is the final result The convulsions which recur at intervals throughout the course of the majority of cases of hydrocephalus result from a condition of functional instability of the cerebral cortex which long continued increased intracranial pressure brings about The convulsions are usually general with loss of consciousness

Mental impairment —All degrees of mental reduction occur from the least noticeable to complete idiocy The more severe forms are met with in cases when cerebral agenesia and porencephaly are associated The psychical reduction is less prominent the greater the age at which the symptoms commence and as a rule the intelligence is far greater than the severity of symptoms (cranial enlargement paresis etc) might lead one to expect Cerebration is usually slow and the disposition placid and periods of somnolence are of common occurrence

Paralysis —The effect of long continued ventricular distension in many cases is to cause degeneration of the pyramidal system and according to its degree the latter entails bilateral spastic paralysis with contracture The first signs of the onset of this event are exaggeration of the deep reflexes and the change in type of the plantar reflexes from the flexor to the extensor response The lower extremities are affected earlier and to a greater extent than are the upper and at one period of the disease a case may present the picture of cerebral diplegic rigidity comparable with that of

Little's disease The upper extremities are affected later The paresis of the limbs is almost always symmetrical and equal upon the two sides Sensibility is generally normal

Vision is interfered with in a considerable proportion of the cases The enlargement of the infundibular portion of the third ventricle by pressure upon the inner borders of the converging optic tracts may cause bitemporal hemianopia with atrophy of the nasal portions of both optic discs this condition subsequently progressing to complete blindness and complete optic atrophy

In rare cases optic atrophy is the result of papillœdema Strabismus is commonly present and it is most frequently convergent Nystagmus is met with in the subjects of hydrocephalus who are blind from optic atrophy and it is of frequent occurrence in *long standing cases in which spastic paresis is well marked*

Headache is rarely complained of and never dominates the clinical picture in children and is never so severe and persistent as that arising from the presence of an intracranial growth Cerebral vomiting is of comparatively rare occurrence

When one considers the *profound anatomical alterations which take place in the* advanced stages of the disease the occurrence in some cases of unusual symptoms indicative of interference with the functions of the cerebellum brain stem and cranial nerves is easily explicable Unilateral or bilateral ataxy vertigo deafness, anosmia and paralysis of cranial nerves are the most important of such unusual symptoms

The signs of failure of the nervous system as a whole usher in the fatal result in severe cases For some days or perhaps weeks before death hebetude may become profound spastic paresis gives place to flaccid paralysis with muscular wasting the deep reflexes disappear and the sphincter mechanism loses its control and subsequently its tone

Diagnosis —On account of the characteristic appearances of the skull this seldom presents any difficulty though in childhood only a careful history will serve to differentiate the congenital from the chronic acquired type of hydrocephalus The enlarged skull of rickets is recognised by its different conformation by the absence of nervous signs with the possible exception of convulsions by the absence of the characteristic change in the percussion note and by the presence of other rachitic signs The rare condition of macrocephaly is not associated with any distortion of the relative proportions of the skull *It should be remembered that an abnormally large head is* hereditary in some families

Prognosis —In all severe and progressive cases the prognosis is hopeless In some of the milder cases the process becomes arrested and the patient may attain to adult life with the possession of all his faculties In cases in which the disease becomes stationary the prognosis as regards mental capacity and the continuance of recurring convulsions has to be considered If the mental capacity at the time of the arrest is fair it is not likely to deteriorate further unless epilepsy is established When mental reduction is marked at the time of arrest any appreciable degree of improvement cannot reasonably be expected *A certain number of cases of mild* congenital hydrocephalus cease to progress and the symptoms retrogress and disappear permanently

Treatment —In those cases in which there is evidence of congenital syphilis *the employment of antisyphilitic treatment is indicated*

The results of surgical interference for the relief of pressure or to attempt the re establishment of a way of escape for the cerebrospinal fluid have been, up to the present so unsatisfactory that many writers and authorities consider such measures unjustifiable It should be remembered however that in severe and progressive cases one is dealing with a necessarily fatal malady and a few encouraging results have been published which appear to justify further investigation Ventricular paracentesis is useless as any relief which results is only temporary and it is not without danger if the intraventricular pressure is raised

(2) CHRONIC ACQUIRED HYDROCEPHALUS

Ætiology —Hydrocephalus usually of the internal type secondary to obstruction in the cerebrospinal fluid pathway may result from a variety of causes Foremost among these is meningitis especially the posterior basic meningitis of infancy and early childhood but it may result from any type of meningitis including tuberculous meningitis in which recovery from the initial disease takes place It is caused by occlusion of the foramina of Luschka and Magendie and results in a uniform dis tension of the entire ventricular system Another group of cases depends upon a primary non neoplastic stenosis of the aqueduct of Sylvius as described by Stookey and others Some of these cases show a proliferation of the sub ependymal glia with constriction of the lumen of the aqueduct In others the ependyma may undergo proliferation with the development of tufts which project into the lumen of the canal and form valve like obstructions to the flow of fluid Again in others the lumen itself may be split up into a number of minute channels hardly visible to the naked eye The ultimate cause of this aqueductal atresia is unknown In a third group acquired hydrocephalus results from the presence of neoplasms of slow growth which obstruct the cerebrospinal fluid channels of these the slowly growing cerebellar astrocytomas of early childhood are the most important Other causes are cysts and slowly growing tumours of the third and fourth ventricles supra sellar (Rathke pouch) cysts and pineal or other tumours of the mid brain

Symptoms —The symptoms of chronic acquired hydrocephalus depend largely upon the age at which the process starts If the malady begins in early infancy the picture is in all respects similar to that of congenital hydrocephalus If it occurs in early childhood before the sutures of the skull have become fused and the bones of the vault indistensible the picture is that of moderate hydrocephalus combined with the symptoms and signs of raised intracranial pressure

Pressure symptoms often begin abruptly after the signs of hydrocephalus have been present for a considerable time Prominent among these are headache usually paroxysmal in character vomiting strabismus and double vision In such cases papillœdema is common and if left unrelieved leads to failure of vision from consecutive optic atrophy which may come on with very great rapidity In long standing cases mental failure may occur and weakness and inco ordination of movement from a combination of disturbances of the pyramidal and cerebellar systems There may be considerable arrest of physical development and in cases extending into later childhood puberty is commonly delayed or complete infantilism may persist

Treatment —In some cases of acquired hydrocephalus the cause can be removed by surgical operation and cure may result To this category belong those due to tumour or cyst formation Various methods of re-establishing the cerebrospinal fluid flow have been devised in cases of stenosis of the aqueduct or occlusion of the meningeal foramina The most successful of these is Torkildsen s operation in which the aqueduct is by passed by means of a plastic or rubber catheter introduced into the posterior horn of one of the lateral ventricles and passing under the scalp to enter the spinal subarachnoid space through the antlanto occipital membrane As in congenital hydrocephalus the different forms of ventriculostomy have proved dis appointing and external decompressions usually only afford temporary relief quickly followed by the added complications of cerebral herniation

(3) ACUTE ACQUIRED HYDROCEPHALUS

This condition results from rapid and severe obstruction to the flow of cerebrospinal fluid in subjects whose skulls are no longer capable of expansion or in the case of children when the expansion of the skull cannot keep pace with the ventricular distension Therefore unlike the congenital and the chronic forms of hydrocephalus

there is little or no enlargement of the head and the clinical picture is that of raised intracranial pressure usually without localising signs

Ætiology —In former times the term acute hydrocephalus was applied to tuberculous meningitis and ventricular distension indeed plays an important part in the evolution of this malady The use of the term in this connection has however fallen into disuse The common cause of the condition is new formation within the skull in such a position as to obstruct the flow of cerebrospinal fluid It is thus most often met with in tumours of the third and fourth ventricles and of the posterior cranial fossa

Symptoms —These are the general symptoms of increased intracranial pressure of rapid onset and great severity The majority of cases present themselves with the symptom complex of headache, vomiting and papillœdema without signs of any local lesion of the hemispheres or cerebellum In severe cases proptosis may be present distension of the veins of the scalp may be seen and the skull commonly has a characteristic cracked pot' percussion note Radiological examination may reveal a mottled appearance of the vault resembling that of beaten silver and there may be some decalcification of the posterior clinoid processes and general flattening of the cavity of the sella turcica The diagnosis is confirmed by ventriculography

Treatment —This is essentially that of the underlying cause

(4) OTITIC HYDROCEPHALUS

This term has been used to describe certain cases of raised intracranial pressure occurring in the course of middle ear suppuration which appear to be due to an abnormal accumulation of cerebrospinal fluid

The condition usually occurs in children and has to be distinguished from cerebral abscess Headache vomiting papillœdema and squint are common but unlike cases of abscess there is little if any toxæmia and the cerebrospinal fluid remains normal except for an increase in its pressure

There is evidence that the condition is caused by a non suppurative thrombosis of the cortical veins or venous sinuses and similar cases have been described as a complication of other localised infective processes *e g* tonsillar infections (see p 1410)

The illness runs a benign course and complete recovery normally ensues The intracranial hypertension may be controlled by repeated lumbar puncture

ENCEPHALITIS

Inflammation of the brain may be met with under widely different clinical associations It may occur as a primary disease or as a complication of known infective processes affecting the system locally or generally and it may occur as an associated event in diseases of the meninges As a primary condition it is met with in a variety of virus diseases of the nervous system pre eminent amongst which is encephalitis lethargica These are described in a later section It is found as the result of infection of the brain with pyogenic organisms derived either from local sources of infection in the neighbourhood of the brain or from pyæmia and it may then be either suppurative (brain abscess) or non suppurative It may occur as a complication of many of the acute specific fevers especially measles vaccinia and mumps In these the encephalitis may only be a part of a general inflammation of the nervous system—an encephalo myelitis Acute encephalitis may be found in rare cases as the sole manifestation of cerebral syphilis

In all forms of meningitis there is some degree of extension of the inflammation into the brain tissue and this assumes an important degree in tuberculous meningitis and in some cases of epidemic cerebrospinal meningitis

The symptoms common to all forms of encephalitis are the general symptoms of severe intracranial disease—headache somnolence coma irritability delirium convulsions and vomiting and, in addition local symptoms of irritation and paralysis the precise nature of which is determined by the position and extent of the lesions

(1) CEREBRAL ABSCESS

Synonym —Suppurative Encephalitis

Ætiology —Suppuration within the brain is never primary but is the result of extension of infection from neighbouring tissues or through the blood stream from foci of infection in distant organs In rare cases the original focus of infection is undiscoverable

The following are the important causal factors

1 *Direct infection* from infected regions in the immediate vicinity (*adjacent abscess*) —The important cause of infection is any form of infective disease in the bones or soft tissues of the head and neck From 60 to 70 per cent of all cerebral abscesses arise in this way By far the most common cause is chronic suppuration in the middle ear and petrous temporal bone particularly when this is complicated by a superimposed acute infection Infection of the frontal or other accessory nasal sinuses is second only in importance to middle ear disease and chronic infections of the bones of the skull suppuration of the scalp orbital cellulitis carbuncles of the neck and face are other causes

Adjacent abscesses are usually solitary and commonly occur in the part of the brain in closest proximity to the primary focus of disease Thus abscesses secondary to ear disease are usually situated in the corresponding temporal lobe or cerebellar hemisphere those resulting from disease of the nasal sinuses in the frontal lobes and so one Exceptions to this generalisation are however met with

The exact manner in which the infection spreads to the brain probably varies in different cases In some it occurs by a septic thrombosis of a vein communicating between the infected region and the underlying brain In others the organisms gain access to the brain substance by spreading along the perivascular spaces from a localised area of meningitis evoked by the primary disease In others still there may be direct spread by continuity through the process of ulceration of the surface of the brain described by MacEwen When the primary disease affects the upper surface of the petrous bone the abscess is commonly situated in the temporal lobe which may be adherent to the tegmen tympani while if the posterior surface of the petrous bone is affected the abscess is usually in the cerebellum In cases both of direct extension and spread through the perivascular spaces the cerebrospinal fluid shows the presence of leucocytes predominantly polymorphonuclear during the stage of invasion indicating that the meninges have been involved even though no symptoms of meningitis are present The organisms responsible are commonly streptococcus pneumococcus or staphylococcus The infection may be mixed Other pyogenic organisms may be found and rare cases are caused by streptothrix infection

2 *Pyæmic states* —Abscesses resulting from infection through the blood stream are termed *metastatic or hæmatogenous abscesses* and comprise from 20 to 25 per cent of the total They commonly arise as a complication of chronic suppuration in the chest such as bronchiectasis empyema or lung abscess Less commonly they occur as a complication of chronic bone disease puerperal septicæmia acute infective endocarditis or other septicæmic conditions Subacute bacterial endocarditis may lead to multiple embolic foci of encephalitis but not to actual abscess formation Rarely metastatic abscesses may arise from localised suppuration in remote parts such as the liver and appendix where there has been no evidence of a pyæmic state It is probable that the 10 per cent of cases of cerebral abscess in which no primary

cause can be found fall into this category the original focus of disease having undergone complete resolution

Metastatic abscesses are commonly multiple but may be solitary They are usually situated in the cerebral hemispheres and originate at the junction of the cortex and subcortical white matter or in the central grey masses They are rare in the cerebellum and brain stem The organisms responsible are streptococcus staphylococcus and pneumococcus and mixed infections may occur

3 *Trauma*—Traumatic abscesses may result from penetrating wounds of the skull, particularly when fragments of metal clothing bone and scalp are carried into the brain Such cases are extremely rare in peace but assume considerable importance in times of war Fracture of the base of the skull may permit infection to gain access to the brain from the middle ear or naso pharynx Fractures involving the inner wall of the frontal sinuses or cribriform plate may be followed by the development of a cerebral abscess after a long latent interval

Pathology—Cerebral abscess—whether adjacent or metastatic in origin—usually commences at the junction of the cortex and the subcortical white matter As it increases in size the surrounding brain tissue is displaced and severe distortion of the brain and ventricular system results The commonest site is the temporal lobe and approximately half of all cerebral abscesses are found in this region a reflection of the importance of middle ear disease as an ætiological factor The frontal lobes and the lateral lobes of the cerebellum are other areas frequently affected Abscess in the parietal or occipital lobes or brain stem is rare

If it has been left unmolested until the patient s death a cerebral abscess may attain the size of a hen s egg or even of a large orange but many lead to a fatal outcome before they attain such dimensions The cavity contains thick greenish yellow pus which is often extremely fetid Commonly the abscess cavity is multilocular and its interior is usually of a greyish green colour and covered with adherent purulent debris The abscess wall varies greatly in character with the age of the abscess In cases of recent origin there may be only a slight line of demarcation between the ragged irregular cavity and the surrounding brain If the abscess has been present for a few weeks a well defined capsule can be seen and this can often be felt by the exploring cannula at operation In chronic cases the capsule may become so thick that the whole abscess can be shelled out of the brain without rupture The pus in such an abscess may become inspissated and sterile The white matter for a wide area surrounding an abscess is very œdematous and may contain areas of softening and fresh abscess formation The more acute the abscess the more marked is the surrounding œdema The surface of the brain overlying an abscess often shows a localised area of meningitis with flakes of purulent lymph adherent to the pia mater

The earliest stages of the development of a cerebral abscess seldom come under direct observation but there is every reason to suppose that the initial process is the development of an area of encephalitis around the nidus of invading organisms In this area there is a mobilisation of inflammatory cells with dilatation of capillaries and œdema Gradually liquefaction and pus formation take place in the centre while a fibroblastic reaction at the periphery gives rise to the abscess wall Outside this again is a neuroglial proliferation together with a diffuse inflammatory infiltration of the brain substance and perivascular spaces

Many cases of abscess are associated with a terminal spreading meningitis and in a proportion of cases rupture may have occurred either into the ventricles or the general subarachnoid space a complication which is invariably fatal within a few hours In adjacent abscesses it is not uncommon to find an associated subdural or extradural abscess which is invariably in direct contact with the primary focus of disease

Symptoms—A cerebral abscess has its origin in inflammation and constitutes when developed a foreign body within the skull Death may result from the effects

of continually increasing intracranial pressure and wide interference with cerebral function or from the spread of the infection from the abscess to the meninges and general subarachnoid space The symptoms may be grouped in four classes (1) Those of local suppuration (2) those of increased intracranial pressure (3) localising signs dependent upon the position of the abscess and (4) those of the terminal extension of the infective process

The onset of symptoms is usually extremely insidious and is apt to be overshadowed by those of the preceding disease The usual sequence of events is that a case of mastoid suppuration or frontal sinusitis does not progress quite as well as it should do as judged by the local condition and gradually the picture of cerebral abscess makes its appearance without it ever being possible to state with certainty where the original illness ended and the complication began Similarly with blood borne infections it is seldom possible to determine with precision the time at which an abscess began to form although occasionally a rigor may mark the time of onset

The earliest and most constant symptom is headache This is characteristically intermittent in the early stages felt across the forehead and in the occipital region irrespective of the site of the abscess especially on rising in the morning and accentuated by coughing sneezing or stooping The pain attains to an agonising degree of intensity and gradually becomes more prolonged frequent and severe until drowsiness begins to dim its severity In some cases a considerable degree of local pain and hyperæsthesia to touch or pressure may be felt over the site of an abscess Occasionally during the months in which a slowly developing abscess is forming there may be periods lasting a day or two of intense occipital pain nuchal rigidity vomiting and fever These disturbances may pass as bilious attacks or influenza but are in reality due to meningeal irritation set up by a deeply seated infection Vomiting is a common early symptom It usually occurs with the headaches but especially in cases of cerebellar abscess it may arise suddenly and with great violence in the absence of any other symptoms Mental changes are common These vary from slight lassitude and a vague feeling of unwellness to drowsiness and ultimately coma Delirium is common during periods of meningismus Double vision is often complained of and is usually an intermittent uncrossed diplopia on lateral deviation of the eyes which results from weakness of one or both external recti

Symptoms of focal disturbance of the nervous system are less constant and usually later in occurrence than the symptoms of general intracranial disorder Epileptic disturbances of any kind may occur with abscesses in the cerebral hemispheres taking the form of generalised convulsions focal fits or petit mal attacks according to the site of the lesion There may be weakness on one side of the body or in one limb or sensory disturbances of a similar distribution Disorders of vision due to the presence of hemianopia may be encountered and disturbances of speech are common in abscesses of the left temporal lobe Where the cerebellum is involved the patient may be aware of awkwardness of voluntary movement particularly with regard to standing and walking and giddiness may be complained of

The patient usually has a strikingly sallow earthy complexion with a slightly cyanotic tint about the lips and nose The tongue is thickly coated the breath extremely offensive the lips dry and cracked and often bleeding from being picked The temperature chart is usually characteristic Fever is present but of a very low degree seldom rising above 100 F and often being subnormal for a day or 2 days at a stretch When it rises above 101 F it will usually be found that this rise is coincident with symptoms of meningism In chronic cases the patient may appear to be completely afebrile but careful recording will usually demonstrate an occasional rise to 99 or 100 F sometimes at intervals of many days Equally valuable is a record of the pulse rate This is almost always unnaturally slow and in no intracranial condition with the possible exceptions of extradural and subdural hæmorrhage is this depression of the pulse rate so constant as in cerebral abscess In persons with a

cause can be found fall into this category the original focus of disease having undergone complete resolution

Metastatic abscesses are commonly multiple but may be solitary They are usually situated in the cerebral hemispheres and originate at the junction of the cortex and subcortical white matter or in the central grey masses They are rare in the cerebellum and brain stem The organisms responsible are streptococcus staphylococcus and pneumococcus and mixed infections may occur

3 *Trauma* —Traumatic abscesses may result from penetrating wounds of the skull particularly when *fragments of metal clothing bone and scalp are carried into* the brain Such cases are extremely rare in peace but assume considerable importance in times of war Fracture of the base of the skull may permit infection to gain access to the brain from the middle ear or naso pharynx Fractures involving the inner wall of the frontal sinuses or cribriform plate may be followed by the development of a cerebral abscess after a long latent interval

Pathology —Cerebral abscess—whether adjacent or metastatic in origin—usually commences at the junction of the cortex and the subcortical white matter As it increases in size the surrounding brain tissue is displaced and severe distortion of the brain and ventricular system results The commonest site is the temporal lobe and approximately half of all cerebral abscesses are found in this region a reflection of the importance of middle ear disease as an ætiological factor The frontal lobes and the lateral lobes of the cerebellum are other areas frequently affected Abscess in the parietal or occipital lobes or brain stem is rare

If it has been left unmolested until the patient s death a cerebral abscess may attain the size of a hen s egg or even of a large orange but many lead to a fatal outcome before they attain such dimensions The cavity contains thick greenish yellow pus which is often extremely fetid Commonly the abscess cavity is multilocular, and its interior is usually of a greyish green colour and covered with adherent purulent debris The abscess wall varies greatly in character with the age of the abscess In cases of recent origin there may be only a slight line of demarcation between the ragged, irregular cavity and the surrounding brain If the abscess has been present for a few weeks a well defined capsule can be seen and this can often be felt by the exploring cannula at operation In chronic cases the capsule may become so thick that the whole abscess can be shelled out of the brain without rupture The pus in such an abscess may become inspissated and sterile The white matter for a wide area surrounding an abscess is very œdematous and may contain areas of softening and fresh abscess formation The more acute the abscess the more marked is the surrounding œdema The surface of the brain overlying an abscess often shows a localised area of meningitis with flakes of purulent lymph adherent to the pia mater

The earliest stages of the development of a cerebral abscess seldom come under direct observation but there is every reason to suppose that the initial process is the development of an area of encephalitis around the nidus of invading organisms In *this area there is a mobilisation of inflammatory cells* with dilatation of capillaries and œdema Gradually liquefaction and pus formation take place in the centre while a fibroblastic reaction at the periphery gives rise to the abscess wall Outside this again is a neuroglial proliferation together with a diffuse inflammatory infiltration of the brain substance and perivascular spaces

Many cases of abscess are associated *with a terminal spreading meningitis* and in a proportion of cases rupture may have occurred either into the ventricles or the general subarachnoid space a complication which is invariably fatal within a few hours In adjacent abscesses it is not uncommon to find an associated subdural or extradural abscess which is invariably in direct contact with the primary focus of disease

Symptoms —A cerebral abscess has its origin in inflammation and constitutes when developed a foreign body within the skull Death may result from the effects

Abscesses situated in the parietal and occipital lobes are rare Except as a complication of osteomyelitis of the skull they are almost invariably metastatic in origin The most important local signs that they give rise to are contralateral sensory loss of a cortical type in the case of parietal lobe abscesses and defects in the contralateral fields of vision in those situated in the occipital region In either case epileptic attacks may occur

Cerebellar abscesses often present great difficulties in localisation The general symptomatology is much the same as in cases where the abscess is situated above the tentorium though on the whole the mental alteration is less and the vomiting and occipital pain more marked in cerebellar cases Nystagmus is a valuable sign which is seldom completely absent and some degree of weakness of a lower motor neurone type on the same side of the face is often present Both these signs however may be found in cases with a localised area of meningitis in the posterior fossa without any abscess within the cerebellum itself The most reliable sign is the presence of hypotonia and inco ordination of movement of the limbs on the same side of the body In bed these changes are most readily detected in the arms but if the patient is well enough to walk the inco ordination may be very evident in the gait It is by no means unusual for a cerebellar abscess to be present for many weeks without producing any detectable localising signs while the general condition of the patient leaves little room for doubt as to the presence of an abscess somewhere

The cerebrospinal fluid is very seldom completely normal in cases of cerebral abscess and examination of the fluid can afford very valuable aid in the diagnosis of doubtful cases Withdrawal of fluid is however by no means devoid of risk and may lead to a rapidly fatal result either by precipitating medullary failure or by causing the abscess to rupture into the ventricle For this reason when the diagnosis is not in doubt lumbar puncture should be avoided and when there is a suspicion that an abscess is present the smallest necessary quantity of fluid only should be withdrawn through a very fine needle The pressure of the fluid is raised and may reach a very high figure The first change to take place in the composition of the fluid is an increase in the amount of total protein from the normal 40 mg per cent to 60 or even 80 mg per cent With this is found a gradual increase in the number of cells to 10 or 20 and rarely more than 100 per c mm At first the cells are almost entirely lymphocytes though an occasional polymorph may be identified in a long search As the number of cells increases the proportion of polymorphs increases until they may constitute 10 per cent or even 20 per cent of the total Finally as the abscess approaches close either to the ventricle or to the convex surface of the brain such a brisk pleocytosis may be caused that the fluid becomes turbid in appearance but is still sterile with a normal or only very slightly reduced content of chlorides and sugar The finding of a turbid cerebrospinal fluid in which no organisms are seen and which remains sterile on culture is always extremely suggestive of a cerebral abscess

Diagnosis —The diagnosis of cerebral abscess has to be made from other complications of suppuration in the vicinity of the brain and from other expanding intra cranial lesions particularly cerebral tumour

The varieties of intracranial complication of neighbourhood suppuration most likely to be confused with cerebral abscess are

1 Acute spreading meningitis
2 Localised meningitis with or without an extradural abscess
3 Infective venous sinus thrombosis
4 Otitic hydrocephalus

1 *Acute spreading meningitis* —The differential diagnosis here seldom presents serious difficulty The high sustained fever rapid pulse delirium and marked neck rigidity all make the recognition of acute meningitis easy Difficulty does however,
